COLLEGE OF SURGEONS OF ENGLAND

VOL. II.

MACROGLOSSIA—ZYGOMA

SECOND EDITION

LONDON

SMITH, ELDER, & CO., 15 WATERLOO PLACE

1887

may be healthy. The tongue hangs forward over the chin, and its surface is constantly dry and the papillæ are prominent. Small hæmorrhagic puncta are seen beneath the mucous membrane, and between the elevations are sores and fissures. The tongue can by an effort be drawn into the mouth, but, except when voluntarily retracted, it is habitually protruded. The oral passage being obstructed, breathing is performed chiefly through the nostrils, which are, therefore, dilated. The constant dribbling of saliva causes a rough, red, eczematous eruption on the skin covering the chin. If punctured, the exudation will appear more serous than bloody. This condition has first to be distinguished from that of acute glossitis, in which the history of some injury or cause, and the rapid onset of the swelling, together with the pain, the glazed appearance of the surface of the organ, which is observed to fill the cavity of the mouth but to protrude but little from it, point to the true nature of the affection. A condition for which true macroglossia has been mistaken, and for which amputation has been erroneously performed, is that which is seen in some idiotic children, particularly in those who are described as 'sporadic cretins,' in whom the mouth remains open, and the tongue lies between the gums or even is advanced beyond them; but the vacant look and absence of all expression, the small forehead and general dwarfed appearance, added to the fact that the size of the tongue does not undergo any increase, should obviate this mistake.

Treatment.—Compression has in many cases effected a cure, and should, at all events, be given a fair trial. This is best accomplished by strips of isinglass plaster placed round the organ, much in the manner of strapping a testicle. Beneath this, small strips of calico, which have been steeped in a solution of alum, tannin, or some other astringent, may be wound round the tongue; or a linen bag may be made to fit the protruded portion and be tied behind the head with tapes. When the tongue can be retained in the mouth, the chin should be supported by a bandage secured over the vertex, and the mouth thus kept constantly closed. All these means are, however, difficult of application, and the alternative of excision will in most cases have to be resorted to. This is best performed by excising a V-shaped portion, with scissors or a bistoury, from the end of the elongated member. The hæmorrhage is not severe, and the vessels are easily secured with cat-gut ligatures, when the edges of the wound

thus made can be brought together by one or more silver wires passed deeply through the substance, thus drawing the parts firmly together, while the edges are superficially united by means of fine wire or horsehair. This is more likely to obtain primary union than any other method, but the *écraseur* or galvano-cautery may be used with the same purpose. The period at which operation is to be resorted to should, if possible, be before dentition has commenced, and the sutures should be removed before suppuration in their track has occurred. The introduction of setons or the injection of astringent fluids is worse than useless. As regards medicinal remedies, there is some advantage in putting the patient on cod-liver oil and some preparation of iron. JOHN H. MORGAN.

MALIGNANT PUSTULE (*Synon.* Anthrax Charbon, Woolsorters' Disease, Mycosis Intestinalis) is a specific affection caught from animals suffering from splenic fever, a disease which occurs sporadically in cattle in this country, but is endemic and very fatal in many other parts of the world. Graminivorous animals, and especially horned cattle, sheep, and horses, are liable to splenic fever, and the disease may spread to those who have to tend the beasts when alive, or to handle their hides and flesh after death. It is in the latter mode that the infection is usually conveyed in this country, where, of late years, the disease has occurred with some frequency among the tanners of foreign hides in Bermondsey, and the sorters of Van mohair in Bradford. It has also been observed in those who have eaten the flesh of infected animals, and instances are on record in which the disease has been communicated by butter or milk, or by the bites of flies. There are two forms of the disease, the external and internal.

1. The *external* form is the one which usually comes under the notice of surgeons. It is generally seen as a characteristic eschar, to which the name *malignant pustule* has been very incorrectly applied, for one of the peculiarities of the disease is an entire absence of pus-formation until the throwing off of the slough. From a few hours to several days, or even weeks, after the contagious material has come into contact with the skin, a small itching red

pimple appears upon some exposed part of the body, such as the face, neck, or arm. A vesicle soon forms upon the papule, containing serum and frequently a little blood. This is either opened by scratching or dries up. Meanwhile the papule grows and becomes an indurated red area, upon which other vesicles form around the first. As the disease progresses, the earlier vesicles sink down, and a slight central depression of a dark dingy purple colour appears, surrounded by a ring of closely set pearly vesicles, two or three deep. This indurated area may attain a diameter of more than an inch. It is usually elevated one-eighth of an inch above the healthy skin around, and the central depression is about one-twentieth of an inch below the level of the adjacent vesicles. Soon, the parts around become slightly flushed, swollen, and œdematous; and this swelling may be so great as to level them with the indurated area, which, however, can always be distinguished by its appearance and hardness. At the same time the lymphatic glands enlarge; but this may be in a great measure concealed by the brawny œdema of the subcutaneous tissues, which is often accompanied, as the disease progresses, by some livid discoloration of the part. There is a remarkable absence of pain in and around the eschar, pricking or a slight gnawing sensation being usually all that is felt.

Constitutional symptoms set in from a few hours to eight or ten days after the appearance of the papule. They bear no exact relation to the amount of local trouble. There is pallor, and in bad cases, cyanosis, with languor and a feeble pulse. Dyspnoea may be observed upon slight exertion, and occasionally there is a cough, or a sense of constriction of the chest. Vague pains and stiffness are complained of in various parts of the body, with chilliness or even rigors. There may be sleeplessness, restlessness, headache, giddiness, and more rarely delirium. In some cases the nervous symptoms are more severe. Convulsions or tetanic spasms occur, followed by coma. In others, the intellect is clear and the voice strong to the last. There is usually loss of appetite, and sometimes vomiting or diarrhoea, with abdominal pain. The temperature is often high, but it is subject to rapid variations. The patient may sink into a typhoid condition and die exhausted, but more often death is the result of sudden syncope, or, where some part of the neck has been the seat of local mischief, œdema glottidis supervenes

and proves fatal by asphyxia. Death usually occurs within five or six days from the beginning of constitutional infection. In favourable cases the general health is not seriously affected. The vesicles may dry up in a few days, and form a black slough, which is separated and cast off by ordinary inflammatory processes.

In some patients, the ring of vesicles may be absent from the eschar, which then consists of a well-defined firm elevation, of a pellucid red colour, with a dingy purple central depression. Except that it is much harder, this form may bear rather a close resemblance to a nævus. A rare variety of the external form is *malignant œdema*, which is said to occur sometimes as a primary disease in those who have eaten the flesh of infected animals, or have inhaled the poisonous matter through their lungs. Beginning as a soft, doughy, pale swelling of moderate extent, it spreads rapidly at its circumference. Vesicles are not always present, and when they appear, are scattered irregularly over the surface. Constitutional symptoms rapidly follow the development of the swelling.

2. The *internal* form presents symptoms which are in most respects identical with those which indicate constitutional infection in the other variety. In this country the *woolsorters' disease* has usually assumed this form. According as the contagion has been received by the lungs or alimentary canal, the disease may take the form of a broncho-pneumonia or gastro-enteritis. In either case it is generally accompanied by great prostration and mental depression; frequently, also, there is lividity of the lips and nails, or more general cyanosis without any physical signs to account for its presence. The incubation may last from two to ten days or even several weeks, and the majority of the cases end fatally in a few days. Occasionally the internal variety is followed by the development of the malignant pustule or œdema upon the skin.

Pathology.—The essential feature of this disease is the presence of a micro-organism, the *bacillus anthracis*, in the tissues. Under the microscope this is easily seen as a well-defined cylindrical body, of a much larger size than the bacteria which are usually found in decomposing matter. The diameter is generally about $\frac{1}{18000}$ th of an inch, while the length varies from $\frac{1}{2000}$ th to $\frac{1}{1400}$ th of an inch, and here and there much longer filaments may be observed. Most of them are straight, but a few are curved or bent at an acute angle. Upon careful examina-

tion some are seen to contain transverse markings, and they have a tendency to break up into segments at these points. Ovoid spores may sometimes be seen in their interior, and occasionally collections of these spores are found in the adjacent tissues. In the external form, the central parts of the eschar are dried up to a leathery substance, while the surrounding skin and the subjacent tissues are infiltrated with fibrinous exudation. Small patches of ecchymosis occur in the deeper layers of the corium, and sometimes in the muscles beneath, but nowhere is there any appearance of pus. The vessels are not affected. The adjacent glands are swollen, and sometimes ecchymosed. The characteristic bacilli, with their spores, abound in the fibrinous exudations beneath the Malpighian layer of the eschar. They are also found in the superficial strata of the corium, and outside the sheaths of the hair-follicles. Although they are probably conveyed by the blood to the other parts of the body, it is rare to find them in the vessels near the eschar or in the blood of the patient during life.

In the bodies of those who have died from either the *internal* or *external* form of the disease, the surface is generally cyanosed and there are signs of rapid decomposition, the blood is thick and dark and does not coagulate. Small hæmorrhages are found in the viscera, and under the mucous and serous membranes. Effusions of blood and serum are met with in the pleural, peritoneal, and other serous sacs. The lungs are congested or inflamed, with nodules of ecchymosis upon the surface or in their substance. In some cases there is œdema of the upper part of the larynx. Blackish raised patches, formed by extravasated and decomposing blood and somewhat resembling the external eschar, may be found studded over the internal surface of the stomach and intestines. They are surrounded by gelatinous infiltrations of the mucous membrane, and in many cases the process of separation by sloughing is already far advanced. The liver and spleen are often large, congested, and softened, and the mesenteric glands may be swollen and ecchymosed. Hæmorrhages may be found in the cerebral and spinal meninges. Upon microscopic examination, the bacilli are found abundantly in the patches of ecchymosis and the surrounding infiltrations. In cases which recover from the constitutional infection, the writer has seen the bacilli in the sputa, sweat, fæces, and urine.

Diagnosis.—In most cases, the characteristic eschar of the external form is easily recognised. The raised indurated area, with its central blackish depression surrounded by a ring of closely-packed vesicles, can hardly be mistaken for any other affection. Further confirmation may be obtained from the painlessness of the swelling, the occupation of the patient, and the finding of bacilli in the serum obtained by scraping the vesicles. The disease is sometimes confounded with a boil or carbuncle, and especially with the acute and very dangerous form of the latter which sometimes attacks the face. Both these affections, however, are from the first painful, and they soon show evidence of suppuration. In the same way, it will usually be easy to distinguish it from an ordinary poisoned wound. When the vesicles are drying up, it may somewhat resemble a chancre of the face, but the history of the case, the rapidity of development, and the absence of tenderness would usually suffice for the recognition of malignant pustule. When the soft parts are much affected, its appearance may approach that of erysipelas or cellulitis, especially where the eschar is small, or, in the case of malignant œdema, where it is absent. Here, however, the occupation of the patient would afford a clue, and a microscopic examination of the serum would probably show the presence of bacilli. There is also a peculiar pallor and a tendency to the formation of cyanotic patches, which is not observed in ordinary cellulitis. In the internal form the diagnosis of isolated cases is very difficult, and they may easily be mistaken for ordinary pneumonia when the lungs are primarily affected, and for enteritis or typhoid fever when the intestines are chiefly attacked. But when several cases have occurred, or where the occupation of the sufferers makes it probable that they have been exposed to the contagion, the peculiar and sudden prostration, together with the tendency to a cyanotic condition, for which the physical signs afford no satisfactory explanation, will be enough to suggest the true nature of the disease, and further evidence may be obtained by the microscopical examination of the blood and excretions.

Treatment.—In the *external* form, it is of the utmost importance to destroy or remove the whole of the indurated area which forms the primary eschar. This is most effectually done by the knife, and care should be taken to dissect away the whole thickness of the affected skin, together with about one-eighth of an inch of the, apparently healthy, adjacent tissue.

When the hæmorrhage has been checked by pressure or ligature, the exposed surface should be examined, and if it should present any appearance of discoloration or ecchymosis, some cauterising agent should be employed, such as chloride of zinc paste (i.e. one part of the chloride to three of flour), or potassa fusa, or the thermo-cautery. In Turkey, where the disease is frequent, the usual plan is to destroy the whole eschar with the actual cautery; and in France the use of potassa fusa, for this purpose, has been strongly recommended by Bourgeois. Success has also followed the subcutaneous injection of the liquefied crystals of carbolic acid. It is generally desirable to have either or chloroform administered, but where the patient objects, or where his languid and cyanotic condition indicates that an anæsthetic would be dangerous, the operation can be performed without this assistance, and it is not attended with much pain. The wound should be dressed with carbolised oil, or boracic acid ointment spread on lint.

Recovery usually follows the removal of the primary lesion, even when the swollen state of the parts around and of the adjacent glands, together with severe constitutional disturbance, proves that the disease is no longer local. Probably, the eschar acts as a nursery from which the infective material passes into the system, and after excision the patient is in a better position to throw off that which has already passed into the circulation. In some cases, in which the surrounding cedema is already excessive, or in which after excision the swelling still spreads, it may be necessary to incise freely the swollen tissue, or resort may be had to the subcutaneous injection of some antiseptic fluid, such as an aqueous solution (1 in 20) of carbolic acid. The same treatment would be required in malignant cedema. Constitutional symptoms should be treated by absolute rest in bed, with a plentiful supply of animal food, such as beef-tea, milk, and eggs. If the heart's action is weak, ammonia and alcoholic stimulants should be freely given. Large doses of quinine are beneficial. The internal administration of sulphite of sodium in 10-grain doses has been recommended, on account of the success which has attended its use in the splenic fever of animals. Where there is evidence of obstruction to respiration from cedema glottidis, laryngotomy should be performed. The subcutaneous injection of morphia may be required in those cases in which sleeplessness is a distressing symptom, and opium may be called for to check the diarrhoea produced by the gastro-intestinal lesions.

Where the lungs are affected, senega and other expectorants will be useful, and the patient may be made to inhale air charged with carbolic acid or some other antiseptic agent.

N. DAVIES-COLLEY.

MALIGNANT TUMOURS.—All malignant tumours are either Sarcomata or Carcinomata, and display their malignancy in similar ways, though to a very varying extent. For, whilst an innocent tumour may, by its weight, size, and position, become dangerous to the comfort and life of the patient, malignant tumours destroy by other means as well. Malignant tumours differ from innocent growths in the following particulars:—1. Mode of growth; 2. glandular affection; 3. dissemination; 4. interference with the general health; 5. local recurrence after removal.

1. MODE OF GROWTH.—All malignant growths tend to *infiltrate* the tissues in which they grow, and it is in their growth by infiltration that they essentially differ from the innocent tumours. They may also be said to grow at their *periphery*, innocent tumours from their *centre*; and, although this is not absolutely true, perhaps, in all cases, still it is a broad fact which generally holds good. In consequence of this infiltration and peripheral growth, malignant tumours are practically never encapsuled, although to the naked eye they may sometimes appear to be so, but actually blend with, and are inseparable from, the tissues in which they develop. They never simply push aside the structures amongst which they grow. This infiltration is more marked in the carcinomas than in the sarcomas, and the latter are, at times, apparently encapsuled; whilst, at the growing edge of the former, the remains of the surrounding structures may be seen entangled in the tumour-growth. But, in addition to its infiltrating mode of growth, a malignant tumour increases with much greater rapidity than does an innocent one. Its blood-supply is large, its cell-multiplication rapid, and within three or four months it may attain a considerable size. The skin covering such a growth is at first simply stretched over it; then, especially in the carcinomas, it becomes dimpled and puckered by the inclusion of the subjacent tissues; and finally, becoming itself infiltrated and adherent, allows of the protrusion of a fungating mass. This protruding growth is often foul-smelling, very vascular, and readily bleeding; and the patient is worn out by the combination of septic conditions with profuse discharge of

blood and pus. Large fungoid masses occur, especially in connection with rapidly growing tumours; for, where the growth is slow, it ulcerates and disintegrates on its exposed surface almost as rapidly as it is produced. This is very evident if an encephaloid cancer be compared with an epithelioma.

A malignant growth may become the seat of inflammatory changes; suppuration and the formation of a definite abscess within the tumour may occur. All the usual signs of inflammation may be present, and the abscess may point and burst, in just the same way as a similar collection of pus in an otherwise healthy tissue. This is especially common in the case of lymphatic glands the seat of new growth secondary to epithelioma.

2. GLANDULAR AFFECTION.—One of the best marked and most widely recognised evidences of malignancy is found in the affection of the neighbouring lymphatic glands. This glandular affection has nothing whatever to do with inflammatory processes, for, although the latter may be present, they in no way bear evidence to the malignancy of the growth. The glands are affected by the production in them of new growth, precisely and in all respects similar to, and identical in structure with, the original tumour; so that in the glands are reproduced, with the most perfect mimicry, all the little varieties of structure met with in the original cancer. Innocent tumours do not so affect the glands.

But although glandular affection may be said, in general terms, to be of common occurrence in the cancerous growths, the question whether the glands shall be so diseased in any given case depends upon two conditions—(a) the character, and (b) the locality of the growth.

(a) *Character*.—Speaking generally, it may be said that the carcinomata much more frequently cause glandular infection than do the sarcomata; but that, of the carcinomata, the rodent ulcers practically never infect the glands, and the adenoid carcinomata not nearly so frequently as the other groups of the same class. The epitheliomata and spheroidal-celled carcinomata most generally cause glandular affection. The sarcomata, on the other hand, do not as a rule affect the glands—i.e. when they occur in those situations in which they most generally come under the notice of the surgeon, as apart from the physician. But one variety, nevertheless—the melanotic sarcoma—does, almost invariably, cause glandular infection.

(b) *Locality*.—Carcinomas in certain localities rarely affect the glands. This is especially true of all the varieties that are found in the œsophagus, stomach, and intestines, as well as in the superior maxillary bone. Sarcomata of the testis, the tonsil, and of the mediastinum, always result in glandular affection, as do, more rarely, similar growths in other situations; whilst sarcomata of the breast, of the subcutaneous tissues, and those growing in or around the bones, almost never infect the glands.

3. DISSEMINATION.—Although malignant tumours, as a whole, are prone to cause metastatic growths, this phenomenon, like glandular affection, is influenced by—(a) the character, and (b) the situation of the tumour.

(a) *Character*.—Rodent ulcers never tend to become disseminated. Epitheliomas and adenoid carcinomas do not become disseminated nearly so frequently as do the spheroidal-celled carcinomas, and, of these latter, the scirrhus growths are less liable to dissemination than are the encephaloid tumours. Of the sarcomas, the round and mixed-celled groups are those which are the most likely to be associated with metastatic growths, and the melanotic variety is in this respect of a very malignant nature. The spindle-celled sarcomas often become disseminated, but not so frequently as the above groups. And, still speaking of the sarcomata, it may be said that the more the tumour tends to become developed into one of the higher forms of adult tissue, the less likely is dissemination, so that the fibro-sarcomata often do not become disseminated at all.

(b) *Locality*.—But, whilst laying due stress on the influence which the structure of the growth exercises upon the question of its dissemination, it must clearly be borne in mind that its locality is also of great importance. Thus, epitheliomas of the lip and vulva are much less liable to become disseminated than are those of the tongue. Carcinomatous growths of all kinds, occurring in the œsophagus and stomach, often run their entire course without metastasis, whilst precisely similar growths, in the testis or in the breast, are extremely prone to become disseminated. So also with sarcomas. Thus, round-celled sarcoma of the testis tends to become most rapidly disseminated, and is altogether of a very malignant nature; whilst a similar tumour in the parotid gland is practically never followed by metastasis. Fibro-sarcomas of the skin and subcutaneous tissues often

run their entire course without occurring in distant organs. Similar tumours in the breast follow a like course, whilst those fibro-sarcomas which occur under the periosteum of the long bones tend to become widely disseminated, and run a very malignant course.

4. AFFECTON OF THE GENERAL HEALTH. There can be no doubt that, in the growth of malignant tumours, the general health does often become very markedly affected, and that, more particularly, the patient loses weight to a very considerable extent. This wasting and loss of health were formerly supposed to indicate a cachectic condition that was typical of cancer; and although this is no longer generally accepted, it is certainly a fact, that a patient with a malignant growth often wastes to an extent which is out of all proportion to the apparent demands made by the disease upon his vital resources. As the growth increases in size and the viscera become the seat of secondary tumours, the emaciation and weakness become more marked. Special symptoms will be developed according to the particular viscus diseased.

5. LOCAL RECURRENCE. — Almost all tumours which show their malignancy in one of the ways already mentioned, are also prone to recur locally when removed; but many other growths which do not tend to become disseminated or to affect the health of the patient, do tend to recur locally and sometimes to affect the glands. Such growths as these are said to have a 'limited malignancy,' and the chief of them are the fibro-sarcomas or recurrent fibroids of the skin and subcutaneous tissues, the rodent ulcers, and, to a less extent, the epitheliomas of the skin surfaces of the body and of the lips. In the section on etiology this question of recurrence will be alluded to, and here the writers will merely say that the liability to recurrence is apparently more than can be accounted for by simply inefficient removal, though this is undoubtedly accountable for a return of disease in many instances. These recurrent growths, when sarcomata, appear to run one of two pretty definite courses—either the interval that elapses between removal and recurrence of each recurrent tumour steadily diminishes, or else it tends to increase. So that a growth may recur at intervals of six, three, and two years, then after a few months, and then in the wound before it is soundly healed. Or, on the other hand, after two, three, or more removals the tumour may never reappear. The former is unfortunately by far the more common of

the two alternatives. When the period of time that elapses between each removal tends to diminish, it will often be found that the character of the tumour varies with each removal, so that whilst the first growth may have been a fibro-sarcoma, the others gradually become more and more cellular, and the last is perhaps composed of nothing but spindle and oval cells. Yet the tumour may never become disseminated.

ETIOLOGY OF MALIGNANT TUMOURS.—It must be owned at the outset that our knowledge of the causation of sarcomata and carcinomata is very defective—in fact, that it is almost entirely hypothetical. There are, nevertheless, several well-ascertained predisposing and exciting causes, which may be shortly discussed.

(1) *Inclusion Theory*, or embryonic hypothesis of Cohnheim.—This theory may be briefly stated as follows. At the time when the various tissues are becoming differentiated in the embryo, it is supposed that more cells may be produced than are required for the proper formation of the growing tissue or organ; that, not being utilised, they may remain in the locality in which they originally grew, and may become enclosed and surrounded by the fully-developed structures in which they are placed. This small mass of germinal embryonic cells may remain quiescent throughout the life of the patient, or may be lighted up into active growth either by the application of some artificial irritation, or by the normal physiological activity of the part excited in a natural manner.

With regard to this hypothesis, it is here enough to say that it is not sufficiently supported by either physiological or histological research to allow of its general acceptance, and that our knowledge of the life of the tissues renders it extremely improbable that masses of embryonic cells could remain in an unaltered condition—i.e. retain not only the formative, but also the vital and inherent properties of embryonic cells, whilst surrounded by tissues which are undergoing daily metamorphosis.

(2) HEREDITARY INFLUENCE.—It is a fact that, in a certain proportion of cases of 'cancer,' a history of similar disease in the same family may be obtained; and, considering that a very large number of patients are absolutely ignorant of the cause of death of even their near relations, it is quite certain that the ascertained proportion would be increased if accurate histories could be always elicited. It must be clearly borne in mind, however, that even if the hereditary nature of cancer were clearly proved.

this would in no way imply that cancer is therefore a constitutional or blood disease, for just as certain local affections, such as club-foot, hare-lip, multiplicity of digits, &c., may be transmitted from parent to offspring, so a purely local tendency to the development of cancer may be inherited. Such a mode of inheritance is clearly indicated in those cases where, not only is the tendency to cancer-development in general traceable, but even to development in the same situation in the offspring as in the ancestor.

(3) EFFECT OF INJURY OR IRRITATION. Whilst the above theories relate to predisposing causes, the effect of injury or irritation may be considered as an *exciting* cause of tumour-formation. There can be no doubt, in the mind of any surgeon of experience, that the effect of injury or irritation in the causation of cancer is no mere hypothesis. How the injury acts is another affair altogether, and here it will suffice to point out merely some well-established examples of the effect of so-called *traumatism*. The occurrence of epithelioma of the lip or tongue is not infrequently preceded by the irritation of sharp teeth; of broken pipes, often very short, and consequently proportionately hot; of syphilitic or simple ulcers, or fissures, &c. Phimosis, and the consequent irritation of the glans and prepuce by retained secretion, may precede epithelioma of the penis. Sweeps' cancer results from irritation of the scrotum by soot; and other such instances will readily suggest themselves.

But, whilst long-continued irritation often precedes malignant growths, it should be especially borne in mind that it is the carcinomata that are specially likely to follow it. The occurrence of the sarcomata, on the other hand, possibly from their growing in the deeper tissues, is not materially influenced by irritations, but rather by direct and sudden injury, especially in the form of contusion. Thus, a blow on the testis may precede sarcoma of that organ, and a similar history is not uncommon in periosteal sarcomas of bone. Again, wrenches, sprains, and effusions of blood often precede the sarcomas of the soft tissues; and it is certainly to be noticed that, where the tumour is preceded by an injury, it is occasionally of a most malignant type. Further, the swelling caused by the injury in many cases does not entirely subside, but passes imperceptibly into the tumour-growth. With respect to this question of injury, it may here be pointed out that there is a definite form of tumour, allied to the sarco-

mata, which is always preceded by an injury and grows in a scar—namely, keloid. A keloid growth is composed of spindle cells and young connective tissue, and cannot be distinguished microscopically from a spindle-celled or fibro-sarcoma. It further resembles the sarcomata in the constancy of its recurrence after removal, and appears, on the whole, to be in the position of a connecting link between the sarcomata and the inflammatory new growths.

(4) PHYSIOLOGICAL ACTIVITY OR DECLINE.—Both carcinomata and sarcomata frequently occur in places where active or degenerative processes are in progress. The sarcomata are found more particularly in connection with growing and developing, or functionally active, organs or tissues—e.g. at the epiphysial ends of the long bones, in the developing kidneys of infants, in the mammary gland during the years of its greatest activity, and in the parotid gland. The carcinomata, on the other hand, are more prone to develop in glands and tissues that are undergoing retrograde changes—e.g. in the breast and uterus towards the end of the child-bearing period, or later. Normally, in such organs there is a gradual disappearance of epithelial tissue, and if by any means its growth is again induced, the epithelium seems to be unable to grow in a natural manner.

So far the various causes which have been discussed are such as may be considered of a general character. But there are certain more definite conditions which influence greatly the *nature* of the malignant growth. The chief of these are—1. Age; 2. Sex; 3. Locality.

1. *Age*.—Speaking generally, it may be said that sarcomata occur in the young and middle-aged, carcinomata in the middle-aged and old.

2. *Sex*.—In addition to those peculiarities which are dependent upon differences in the sexual organs, certain malignant growths of parts, that might be called indifferent to either sex, are very differently predisposed to tumour-formation in the male and the female. Thus, epitheliomas of the lip and tongue are much more rare in women than in men.

3. *Locality*.—Whilst some organs and localities are frequently attacked by sarcomata, the occurrence in them of carcinomata is unknown. This difference may be dependent upon the absence of any epithelium from which an epithelial growth can start, and is well instanced in the case of the long bones, for, in these, sarcomatous growths are frequent and carcinomata never occur.

On the other hand, the tongue is very rarely attacked by sarcoma, but frequently by carcinoma, although the elements for the development of each are present. Again, in two glands so nearly identical in structure as the parotid and submaxillary, one—the parotid—is frequently the seat of new growths of a malignant nature, the other but rarely. In a similar way, some bones are never attacked by sarcomata, others frequently so. Some organs—e.g. the lungs and spleen—are practically never the seat of primary cancer; others—e.g. the liver and the testis—are liable to be attacked by each of the two great classes of the malignant tumours.

Although all the preceding causes may be recognised as resulting in the production of malignant tumours, it is, nevertheless, difficult to understand the exact manner in which they act. Various explanations have been offered, but none of them are entirely satisfactory. In considering this subject, it must clearly be kept in mind that the most marked character in which any tumour differs from a simple overgrowth of the tissue is, that it grows *independently of the mother-tissue* from which it originated. Under normal conditions, the influence of the mother-tissue in determining the fate of any newly-formed cells cannot be too highly estimated, and is most clearly evident in many pathological and physiological processes. Thus, in the union of a fracture, it is the influence of the bone-tissue that causes the inflammatory exudation of leucocytes to become organised into bone; in wounds of tendons, the same influence is at work, and out of precisely similar cells tendon is formed. In the ordinary every-day process of nutrition, it is the influence of the mother-tissue that causes all growth and development to take place on the exact type of the pre-existing structure. In the growth of any tumour, but more particularly of a malignant one, it is this influence that is most notably absent. And it is readily conceivable that any given tissue or organ may, by an inherent instability of its structure, be disposed to tumour-growth, or that this instability and deficiency in control over the processes of growth or development may also be induced by any of the causes just enumerated.

But, supposing such a theory as the foregoing to be true, does it satisfactorily account for the apparently independent life of the tumour-cells, when transplanted into different organs from those in which they originated? If the cells were capable of growing in any organ to which they may

be transplanted, as they seem to be at first sight, then tumours would be certainly inoculable, either in the same animal in which they commenced to grow, or in any other into which they might be transplanted. This, however, is not the case. If a portion of a growing tumour be transplanted into another animal from that in which the original tumour grew, it never attains any appreciable size, and acts in a manner entirely different from the original growth. Further, in the case in which secondary deposits occur in one organ and not in another, when, so far as can be ascertained, each has been equally exposed, we are justified in supposing that the exemption of the one is due to the fact that its tissue yet exercises a controlling influence over all cells that may be brought into contact with it.

Are the causes, then, that excite cell-growth to be neglected? Certainly not. For had no undue cell-growth been excited, no greater strain would have been thrown on the mother-tissue than it could have borne, and it is conceivable that the very multiplicity of the cells may tend to emancipate some of them at least. In this way the effect of an injury or irritation in producing tumour-formation would be of a twofold nature. Firstly, more cells would be produced than could be controlled by a mother-tissue previously deficient in vital power; and secondly, the injury might itself inflict the necessary damage on a tissue already predisposed. In a similar manner, the development of tumours at the growing ends of bones, and in functionally active glands, may be brought about by a greater increase in the number of the cells than can be properly regulated by a mother-tissue inherently predisposed to tumour-growth.

It will thus be seen that this theory involves a predisposition to tumour-formation in any given organ or tissue. This tendency may, as already explained, be inherited or congenital, but not necessarily so; for it is conceivable that the condition of a tissue may vary from time to time, and that tumour-growth only occurs when all conditions, both exciting and predisposing, are favourable.

Moreover, this theory assists us in understanding the *recurrence* of growths. These have hitherto been explained by supposing that certain cells are left behind, and that these in the future take on active growth. Such a theory appears very difficult of belief, and is open to the same objection as Cohnheim's inclusion theory. It

is scarcely conceivable that tumour-cells should remain in any organ or tissue for five, ten, or more years—for such times may elapse between removal and recurrence—and yet maintain their own individuality; besides, it is noticeable, in the sarcomata, that the cells of the secondary growth often differ materially from those of the primary one. It is much more likely that a sufficient amount of the surrounding mother-tissue is not removed, and that the same or a similar process of emancipation of cells from its influence again takes place as that which resulted in the production of the original tumour. Thus, when a carcinoma of the breast is removed, if the whole of the gland be not taken away, we know that the growth is much more likely to recur than if the operation had been a thorough one. The explanation of this would be that the whole gland was predisposed, and it was the influence of the remaining diseased part that reproduced the tumour.

Treatment.—There is but one treatment for a malignant growth—namely, removal. When once the diagnosis has been made, all palliative treatment must be abandoned. As a rule, removal should not be attempted unless (a) the whole of the disease can be taken away, unless (b) the glands are not too extensively affected to admit of similar radical treatment, and unless (c) there is reason to believe that no metastatic growths are present in the viscera.

In speaking of treatment, it is well also to mention that in not a few cases the development of malignant tumours can be obviated. Thus, no ulcer of the tongue, caused by either a sharp tooth or by syphilis, should be permitted to remain unhealed; increase in size of a previously quiescent wart or mole should be met by immediate excision; and whenever any reasonable doubt exists as to whether any given swelling is inflammatory or due to malignant growth, an exploratory operation should be undertaken without unnecessary delay, and if the case still remain doubtful, removal should certainly be recommended.

Treatment of Growths in Lymphatic Glands.—In all cases where the glands are evidently affected, they should, if possible, be removed. Such operations are often difficult, and, in their performance, the surgeon is liable to be led into much deeper and more dangerous regions than he might expect from an external examination of the growth. The frequency with which carcinomas in some localities affect the glands (especially carcinomas in the breast and on the lip and tongue), has caused some sur-

geons to advise that in all cases of carcinoma in such regions the glands in the neighbourhood should be removed. It is certainly true that, even where no diseased gland can be detected by the most careful manipulation, there may be nevertheless considerable glandular disease. Thus cases are not infrequent in which glands, hardened and enlarged, have been detected only after incision of the superjacent skin and fascia. And, in other cases, glands which, before being cut open, when handled free from the surrounding tissues, appeared entirely normal, have on section been found to contain minute masses of epithelial cells. Indeed, it is evident that, where the cancerous deposit is yet microscopic in amount, it cannot be detected by the naked eye. It follows, therefore, that in no case can it be certainly stated that the glands are not the seat of secondary growth.

Excision of a malignant tumour with a knife or other cutting instrument is the most usually applicable method of removal, the advantages being that a clean-cut surface is left, that the amount of tissue to be removed can be readily regulated, and that the whole operation is completed at once and painlessly.

Removal by caustics is not now so much resorted to as formerly, but there are not a few patients who will submit to the use of these agents, yet who will not tolerate a cutting operation. For such, this method is often applied with benefit, although otherwise, except in rare instances, it has no advantage over excision with the knife.

Electrolysis is useful in cases similar to those in which caustics may be used.

Prognosis after Excision.—From what has been already written in an earlier part of this article, it may be gathered that the prognosis varies according to the nature and situation of the new growth. No general rules are applicable to all cases.

Question of Partial Removal.—The question not infrequently arises whether an operation should be done, when it is evidently not possible to remove entirely either the original tumour or else the secondary growth in the glands, more especially in those cases where the patient suffers great pain, or where there is a large fungating and foul-smelling tumour. There can be no doubt that, in many such cases, partial operations are both justifiable and advisable. See CARCINOMA; SARCOMA. W. MORRANT BAKER.

ANTHONY A. BOWLBY.

MAMMARY ABSCESS. See BREAST, Diseases of the.

MARTIN'S BANDAGES are made of pure rubber, and are quite free from sulphur. They are used to exert pressure on tissues which are indurated owing to long-continued chronic inflammation and passive congestion, to compress joints and bursæ which are the seats of chronic effusion, and to support varicose veins; for the latter purpose they are admirable substitutes for elastic stockings.

Rubber bandages are largely employed in the treatment of callous ulcers of the legs, either to support varicose veins, if there be any, or to promote the absorption of the chronic inflammatory products in the edges of the ulcers. The bandages should be worn during the day only, and should be placed in direct contact with the sore; at night, the bandages should be removed and a simple dressing, free from grease, should be applied to the ulcer. The india-rubber bandages are spoiled by grease, so it is most important that ointments should not be used in combination with them. The bandages must be kept very clean; when removed at night, they should be well sponged with tepid water and then hung up to dry. In the morning, before the patient gets out of bed, the leg and ulcer should be washed and dried; the bandage should be applied in a simple spiral from the ankle to the knee, and care must be taken that it is laid on evenly, and only as tightly as can be done without stretching the bandage. When the patient gets up the leg will swell a little, and so stretch the bandage sufficiently to obtain all desirable compression.

The india-rubber bandages retain the perspiration, and the latter is often irritating enough to cause an attack of eczema in a tender skin; should this happen, the bandage must be discontinued and the eczema treated. The bandage may be subsequently tried cautiously, and it may be found that the leg has become tolerant of it.

As a support to varicose veins, the bandage must be applied as above described.

The bandages may be obtained in lengths varying from three to twenty-one feet; in breadths of two and a half or three inches, and in three different gauges of thickness.

BILTON POLLARD.

MASON'S SPLINT for excision of the elbow consists of two pieces of perforated metal, moulded to fit the upper arm and forearm respectively, and so jointed as to permit the movements of flexion and extension at the elbow and of pronation and supination of the forearm. The splint

should be applied to the inner side of the limb. Within certain limits it is possible to adapt it to the size of the limb for which it is required.

MASSAGE or SHAMPOOING. —

Definition.—Massage consists of a more or less forcible kneading, pressure, or alternate compression and relaxation by the operator's hands, of the soft tissues of any part of the patient's body. Movement or manipulation of the joints is not included. See MEDICAL GYMNASTICS; BONE-SETTING.

Much mystery has generally been associated with the art of rubbing, from the fact that till recently few medical men have practically studied it. Hence, it has been too often left in the hands of so-called 'professional' or 'medical rubbers,' each of whom has been allowed to do as he liked, even when employed by a medical man.

Object.—In most cases, massage is employed to improve local nutrition in a wasted limb, to increase the circulation when languid, and to accelerate the re-absorption of effused products, the result of inflammation or chronic congestion.

Physiology.—Massage induces a more rapid flow of the blood and lymph in any given region of the body; this is chiefly due to contraction from irritation, followed by relaxation of the capillaries and smaller blood-vessels which are controlled by the vaso-motor nervous system, but no doubt the mechanical pressure has a direct influence on the larger veins and lymphatics. By perseverance with friction for a few minutes, the previously cold and clammy limb can be made to glow with natural warmth, an effect which will last for hours in some cases, in others for a few minutes only. If sufficient pressure is exerted in the rubbing, not only the skin and subcutaneous tissues are influenced, but also the deeper lying organs, as the muscles, &c. Rubbing is also employed in chronic constipation due to deficient peristaltic movements of the bowels.

Classification.—Massage has to be modified according to the effect it is desired to obtain, and can be roughly classified as follows:—

(a) For deficient or languid circulation, œdema, and chronic congestions of the extremities.

(b) For muscular paralysis or paresis.

(c) For perverted action or inactivity of the skin.

(d) For chronic thickenings around diseased or injured joints.

(e) For chronic constipation or obstruction of the bowels.

(f) For the relief of pain.

(a) *For deficient or languid circulation*, nothing is more efficacious than the manipulation known as 'fulling'; it is effected by a rapid, transverse, to-and-fro gliding of the two palms alternately on opposite sides of a limb, which is at the same time as firmly compressed as possible. If the leg is to be 'fulled,' the operator begins close to the groin and gradually works his way down to the foot, rapidly moving the hands to and fro. The first time, the hands should be on the outer and inner aspects of the leg; the next, they should be placed higher on one side and lower on the other; the third time, this position is reversed; and finally, the hands are placed anteriorly and posteriorly to the limb. The patient must let the limb remain perfectly passive, so as not to resist the manipulation. 'Fulling' is done either on the bare skin or through some thin underclothing. In chronic congestions and œdema of the extremities, *firm strokings upwards* with the palms, used alternately, are useful; here the skin must be protected from abrasion by olive oil, vaseline, &c.

(b) *For muscular paralysis or paresis*, several manipulations are employed. 'Kneading' is a combination of grasping with large pinching and pressure by the two hands, used alternately, so that whatever is left of the wasted muscles is thoroughly squeezed and moved about. In 'kneading,' the four fingers kept close together should act as one, against the thumb and its thenar mass; care must be taken really to reach the muscles by exerting sufficient pressure, at the same time that the skin is not unduly pinched so as to cause pain. In treating adults, the operator's labour is facilitated if he throws his weight into each grasp of the hand.

'Circular friction by the thumb' is most useful when the space occupied by the wasted muscle is small, as in the case of the anterior tibial muscles, or of those on the anterior and posterior aspects of the forearm, &c. It is, however, equally efficacious for large muscles, as the quadriceps extensor of the knee or the glutei. The operator's thumb-end is firmly placed on any given spot, and, while considerable pressure is exerted, small circles, a half to one inch in diameter, are described ten times from right to left and ten times from left to right. A spot an inch higher or lower, or to one side, is then treated in the same way, and so on until every part of

the muscle or group of muscles has been thoroughly manipulated. The pressure exerted by the thumb can be increased, if necessary, by placing the other thumb on its nail. The skin must always be protected from abrasion as already described. The muscles of the forearm or the anterior aspect of the tibia require from ten to fifteen minutes to be thoroughly rubbed by this method.

Tapping or beating muscles with india-rubber hammers or flat-headed wooden sticks, much employed on the Continent, is less efficacious than the human hand properly instructed.

(c) *For perverted action or inactivity of the skin*, simple rapid to-and-fro frictions with the palms, with or without oil, employing but slight pressure, are easily carried out.

(d) *For chronic thickenings around diseased or injured joints*. — Upward 'gliding friction' firmly applied with the palms and fingers around the whole joint, following its contour and the course of the adjacent tendons, is most beneficial; here also the skin must be protected by oil, &c. Fifteen to twenty minutes should be devoted daily to a large joint such as the knee.

(e) *For chronic constipation or obstruction of the bowels*, massage is most useful when the large intestine is at fault. The patient should lie on the back with the head and shoulders well raised, and the hips and knees flexed and supported by pillows so as to relax the abdominal walls as far as possible. A thorough kneading of the whole abdomen is then easily done, by the operator's hands alternately grasping and relaxing as large a portion as possible of the abdominal walls and the underlying intestines, one hand following the other as in kneading dough. To act specially on the colon, its course should be followed by the palms, which, while exerting considerable pressure, should glide upwards from the right iliac region to the right ribs, then transversely across the epigastrium to the left flank, and then down to the left iliac region; after a little practice, the left hand ascends, the right hand crosses and the left hand descends with great ease and rapidity, especially if the abdomen is covered by the night-dress. The operator should stand on the right side of the patient.

(f) *For the relief of pain*, firm 'stroking' from above down with the flat palms, used alternately, is always soothing. Nearly all the previously described manipulations

are best ended by a score or two of such firm strokings.

General remarks.—As a rule, the patient should feel more comfortable and rested after being rubbed, and the infliction of pain must be avoided if possible. In fat patients, bruising of the skin frequently occurs, but is of no consequence. In some affections, especially in infantile paralysis, the patient will often for the first week or two, or longer, complain of considerable pain while being rubbed, but afterwards the discomfort gradually ceases, and the rubbing will become, on the contrary, actually comforting and soothing. To effect a good result, massage for a half to one hour, once or twice daily, must be persevered with for at least a month or longer. An intelligent nurse or friend of average strength can be readily taught all the above manipulations in one or two *séances*. BERNARD ROTH.

MASTOID CELLS, Suppuration in the. See EAR, MIDDLE, Diseases of the.

MASTURBATION has been defined as 'the production of the sexual orgasm by unnatural means.' Although this vicious habit is one indulged in by both sexes, it is more particularly in males that the surgeon is called upon to interfere. In the case of young children, the irritation of a long prepuce or even the accumulation of discharge beneath it, often leads to manipulation of the parts, and thus lays the foundation of the habit. When it is suspected, the child should be stripped and watched for a few moments, when in all probability the hand will stray to the genitals and unconsciously manipulate them, causing an erection of the penis. But when this is not observed, undue elongation of the prepuce and unnatural development of the parts should lead to the suspicion that, even at a very early period of life, masturbation may have become an unconscious habit. The remedy at this stage is circumcision, and fortunately it is generally a radical cure, for not only is the cause of irritation removed, but the soreness consequent on the operation prevents the child from manipulating the parts, and thus the habit is broken through.

The same treatment applies to much older children. But the cure in their case is not so certain or so immediate, and a recurrence to the practice as soon as the penis is sound should be watched for; on the least suspicion the penis should be freely blistered, and this should be repeated until the practice is entirely discontinued. Excessive masturbation, in children of about nine or

ten years of age, sometimes leads to serious consequences, amongst others the occurrence of epileptic convulsions. It is a fact that the convulsions will entirely cease after the operation of circumcision, and recur so soon as the patient has recovered from that operation, indicating no doubt a resumption of bad practices. At a later period of life, amongst lads who are approaching puberty, the surgeon has frequently to deal with cases of self-abuse. Too often the habit has been learned at school, and has been indulged in without knowledge either of its sinfulness or evil effects. It is a serious question how far this acknowledged vice in schools might be prevented by timely warning, given either by the parent or the medical attendant, to the lad before embarking on school life. Be that as it may, it is certain that the surgeon has often to deal with cases in which the habit has become inveterate and most difficult to break through.

In young adult life, sometimes the discovery is made on the confession of the patient, who has been probably alarmed by reading some filthy quack publication on the subject. In such a case it is the surgeon's duty to allay the unreasonable alarm of the patient, holding out to him confident hopes of ultimate cure. It will be found, in very many cases, that the occurrence of nocturnal emissions is the prominent symptom which arouses the patient's fears. In the first place, he should be convinced that within certain bounds these are not harmful. He should then be instructed to avoid, if possible, turning on his back during sleep, and the old-fashioned plan of fixing a cotton reel over the lower part of the spine, thus awakening the sleeper if he should turn over on his back, is not to be despised. If possible, he should get into the habit of voiding his urine in the early morning hours. The application of nitrate of silver to the prostatic urethra is also of service, as also the passage of a full-sized metal bougie. All these plans, combined with careful attention to the general health, cold bathing, good exercise, and the cultivation of pure morals, will help the patient to emerge from the despair in which this unhappy habit has plunged him; and, if an immediate cure be not effected, at any rate his mind will be impressed with the idea that active measures are being taken for his restoration. See SPERMATORRHOEA.

In more advanced cases, where the habit has been long confirmed, the constitution thoroughly undermined, and the mental powers impaired, it becomes a question

whether the mental condition is not the incentive rather than the result. Self-abuse amongst the insane is a well-recognised fact, and it is also understood that the period of puberty is fraught with danger to those who have inherited mental infirmity. It can be, therefore, readily believed that, in these extreme and apparently hopeless cases of masturbation, insanity is at the bottom of the disease. From a surgical point of view, little can be done. Constant blistering of the penis is about the only course to be adopted, and that, it is to be feared, affords at best only a temporary alleviation. Vigilant supervision, especially at night, which can hardly be obtained outside the walls of an asylum, and the use of locked gloves are also essential. The administration of bromide of potassium has been much advocated, but in the majority of bad cases it will be found of little use. PAUL SWAIN.

MAXILLA, SUPERIOR, Fracture of the. *See* FACE, Fracture of Bones of the.

McINTYRE'S SPLINT is a double inclined iron trough, adapted to fit the back of the thigh and the upper two-thirds of the leg; below this the splint is continued as two side-pieces, with slots in them along which the foot-piece may be moved. The foot-piece can be firmly fixed at the place desired, and the angle at the knee can be increased or diminished as required.

MEATUS AUDITORIUS. *See* EAR, EXTERNAL, Diseases of the.

MECKEL'S GANGLION, Removal of. *See* NERVE AVULSION; NEUROTOMY.

MEDICAL GYMNASTICS.—Gymnastics were first scientifically applied in the treatment of disease by Peter Henry Ling, a Swedish patriot, who died in 1839. He devised a system of exercises, based on anatomy and physiology, by which every voluntary muscle or group of muscles in the body could be brought into action. Ling classified all exercises into—(1) *Active*, which were motions effected by a voluntary effort of the patient; (2) *Passive*, which were those executed on the patient by the surgeon or trained assistant; and (3) *with assistance*, constituting an intermediate class which were partly active and partly passive; thus, in a partially paralysed limb, there may be still some voluntary contraction left in a given muscle, but not sufficiently strong to flex or extend its joint without the help of a second individual. For further information on *Passive* exercises, *see* MASSAGE.

During the voluntary contraction of a muscle, the patient may overcome a yielding resistance offered by the surgeon's hand, or the patient can resist, gradually but continuously giving way, while the surgeon slowly elongates the previously contracted muscle. Thus, taking the biceps and brachialis anticus muscles of the arm, the surgeon can resist by holding the wrist, while the patient slowly flexes the previously extended elbow, which is described as 'surgeon resisting' (S. R.). The flexed elbow can be slowly extended again by the surgeon, while the patient continuously resists and gradually yields; this is described as 'patient resisting' (P. R.). In some exercises the weight of the limb or part moved is, at first, a sufficient resistance. After the power of the weak muscle has been improved by exercise, greater work is obtained by S. R. or P. R. It has been thought that in some cases S. R. exercises are indicated rather than P. R. ones, but, so far as the writer's experience goes, the difference in efficacy, if any, is slight.

Medical gymnastic exercises should be done slowly, without any sudden jerking, and the patient's respiration should continue regularly the whole time. When P. R. or S. R. exercises are practised, the patient should count slowly aloud one, two, three, &c., which prevents him holding his breath, and obviates all risks of hernia, strains, or other injury from unaccustomed movement.

A brief description of 'medical gymnastic' exercises which are useful to the surgeon will be given, all of which can be carried out without special apparatus by the employment of a little ingenuity. For the medical gymnastics of the spine and thorax, *see* ANTERO-POSTERIOR SPINAL CURVATURE; LATERAL SPINAL CURVATURE; PIGEON-BREAST.

ANKLE-JOINT.—The patient sitting, has the leg supported on a chair with the foot projecting beyond. *Flexion*, *extension*, *adduction*, *abduction*, and *circumduction* are executed either voluntarily by the patient or passively by the surgeon; if the former, when the patient is strong enough, also with S. R.

ELBOW-JOINT.—The upper arm being fixed by the surgeon against the table on which the patient lies, *flexion* or *extension* is easily resisted by the surgeon's other hand, the elbow being either flexed or extended to begin with. *Pronation* and *supination*, also *flexion* and *extension*, of the Wrist present no difficulty, if a little time and attention are devoted to carrying out

similar exercises to those already described. The same remarks apply to *flexion, extension, &c.*, of the individual *Fingers*.

Each movement should be repeated some six to twelve or twenty-four times, according to circumstances, and about three-quarters to one hour daily be devoted to the treatment in order to obtain satisfactory results. Throughout all these exercises, care should be taken that, when the patient is trying to contract (i.e. exercise) a muscle, he is not allowed to involuntarily contract other stronger or normal muscles, which should remain at rest.

HIP-JOINT.—The *extensors* (glutei) are efficiently brought into action by the patient lying prone and slowly raising the leg, with the knee kept extended, from off the ground or table on which he is lying. In this same position, *circumduction* of the hip, from right to left and *vice versa*, is easily done. At first, sufficient resistance is offered by the weight of the limb; later, as the patient gains in strength, the severity of the exercise can be increased by the surgeon's hand pressing downwards against the back of the heel (S. R.), or by placing a double bag of shot over the tendo Achillis, a weight of from two to five or ten pounds being generally sufficient. The *abductors* of the hip are obliged to work by the simple expedient of making the patient lie on his side, and do the hip-circumduction with the uppermost leg. The *flexors* are exercised while the patient is lying on his back with the knee extended, either voluntarily or by a lightly applied back-splint. *Inward and outward rotation* of the hip are too simple to require description.

KNEE-JOINT.—The *quadriceps extensor* muscle is made to contract while the patient, lying supine, has the knees flexed, and the legs hanging vertically over the end of the padded table on which he lies. One knee is slowly extended; if the weight of the leg is too great, the surgeon assists by partially supporting the foot, while the patient voluntarily performs as much of the movement as he can. The *flexors* are brought into action by the patient lying prone, and trying to raise the foot from off the ground by slowly flexing the knee, with S. R., if necessary, applied to the back of the heel.

SHOULDER-JOINT.—*Circumduction* from before backwards, which brings nearly all the shoulder and scapular muscles into play, is best done while the patient is lying supine on a padded table, the elbow and

wrist being kept extended either voluntarily, or, if that is impossible from weakness of their muscles, by means of a light anterior wooden splint.

To bring the *scapular* muscles into action, the patient should lie supine, with the arms carried down by the sides of the trunk, or abducted at right angles to the body, or extended upwards by the sides of the head; he has to resist the arms being brought forwards by the surgeon (P. R.) from one of the above commencing positions, and then slowly to return them to the initial position against the surgeon's gradually yielding resistance (S. R.). The elbows are to be kept well extended the whole time, as described above, and the surgeon should grasp the patient's wrists. The rhomboidei and subscapularis muscles are chiefly brought into action in the second movement, with the arms at right angles to the trunk.

BERNARD ROTH.

MEDICINAL ERUPTIONS.—Many drugs and chemicals give rise to eruptions, sometimes after being taken in medicinal doses for a considerable period of time, when the system may be supposed to be saturated with them; sometimes they occur after a single dose has been taken, betraying a peculiar susceptibility on the part of the patient (idiosyncrasy).

1. *Iodine, Iodide of Potassium, and other Iodides* may give rise to—(a) erythematous patches ('iodic roseola') on various parts; the eruption may pass into a papular form, with large disseminated papules, slightly elevated, seated on a reddened surface, the whole not unlike urticaria; (b) purpuric eruptions, often assuming a petechial form, especially affecting the legs; (c) vesicular eruptions (rare), said to resemble eczema; (d) bullous eruptions on the head, neck, and upper extremities, the bullæ tending to be hæmorrhagic; (e) pustular eruptions resembling those produced by bromides.

2. *Bromine, Bromide of Potassium, and other Bromides.*—(a) An erythematous eruption; (b) a maculo-papular eruption closely resembling a syphilide; (c) a bullous hæmorrhagic eruption; (d) pustular, acne-like eruptions, usually on the face or chest; also an eruption which has been described as confluent acne. At its height, it is characterised by round flattened elevations covered with moist epidermis, not unlike that in condyloma, or with thick brownish crusts, on removing which the surface is seen to be dotted with minute collections of pus; the lesions are surrounded by a dark-red areola,

3. *Belladonna* may give rise to an eruption partly erythematous, but partly scarlatiniform—i.e. minutely punctate. It occurs in sharply defined palm-sized patches, which usually affect the upper part of the body; there is no burning or itching complained of, and desquamation does not follow.

4. *Chloral*.—An erythematous patchy eruption, with heat and itching, chiefly affecting the neck, front of the chest, the larger articulations, and backs of the hands and feet. Urticarial, papular, vesicular, and purpuric eruptions have also been described.

5. *Copaiba*.—The eruption generally takes the form of a roseola, selecting the hands, arms, feet, knees, and abdomen. The lesions are slightly raised to the touch, and, being in some instances isolated, may resemble urticaria; itching is present, and the skin may smell of copaiba. The eruption is sometimes taken for macular syphilis.

6. *Cubebs* may give rise to a similar eruption, but it is more generalised and does not itch.

7. *Quinine*.—Erythematous, papular, urticarial, and purpuric eruptions have been noted.

8. *Salicylic Acid*.—(a) Diffuse erythema, with œdema of the eyelids; (b) vesicles and pustules on hands and feet; (c) purpuric eruptions.

9. *Tar, Carbolic Acid, Turpentine, Resin*.—A general erythematous urticarial eruption has followed Lister's process. Turpentine produces a similar eruption with great itching, preferring the face and upper portions of trunk. Eruptions have been noticed to be caused by other drugs, as arsenic, cannabis indica, digitalis, mercury, opium, santonin. ALFRED SANGSTER.

MENINGITIS. See ENCEPHALITIS.

MENINGOCELE.—By this term is meant a hernia of the membranes of the brain through some part of the parietes

of the cranial cavity. The sac consists of dura mater and arachnoid, with a covering of skin. Occasionally an interval (subdural), more or less considerable, exists between the two membranes, or, on the other hand, they may be so fused together that it is difficult to differentiate the wall of the sac into two distinct layers, especially at that part most remote from the opening in the skull. Hence, possibly, the presence of arachnoid has been overlooked in those rare instances in which the sac has been described as being formed of dura mater alone. Mr. Bryant mentions such a meningocele as being in Guy's Museum, No. 1563⁶⁰; but on examining this specimen a considerable protrusion of arachnoid is visible, which is disposed in loose folds at some distance from the dura mater. This separation of the two membranes is probably due to the way in which the preparation was mounted when fresh. Mr. Shattock states that after careful inspection of many cases of spina bifida (the analogous condition in the spinal region), he could not say that the arachnoid membrane was ever absent. Although it is conceivable that the wall of a cranial meningocele might be formed of dura mater alone, it does not appear probable that this ever happens.

The hernial sac is distended with cerebro-spinal fluid, and sometimes contains a part of the brain or cerebellum. In the latter case the tumour is known as an *encephalocele*; and if a case of encephalocele be complicated by the co-existence of a hydrocephalic state of the ventricles, then the term *hydrencephalocele* is employed. These tumours are always congenital, are more frequently met with in male than female children, and are due to an arrest of development of the bony wall of the cranial cavity at the point at which they appear. They vary from the size of a marble to two or three times the size of the head of the child; in fact, they may be so small as not to attract attention or so immense as to produce almost complete exencephalia. In the *Pathological Transactions*, vol. xvi., the late Dr. Murchison related a case in which the whole of the cranial portion of the occipital bone was deficient, causing an enormous bag to depend from the back of the head, containing the whole of the brain except a portion of the thinned, expanded, and stretched out anterior lobes, which alone occupied the diminished cranial cavity.

The most usual seat of these tumours is in the median line, especially in the occipital region. They may, however, occur at any other point, as through the frontal suture

or the fronto-nasal suture, in the temporal region, or dipping down into the nasal cavity or pharynx. In the last-named situations they have been mistaken for polypi. Statistics illustrate the frequency with which these malformations occur in the occipital region. The mode of development of the tabular portion of the occipital bone is worthy of note in connection with this point. It is developed from four nuclei, which appear about the eighth week of foetal life. At birth this tabular portion consists of a flat plate, with fissures running in nearly to the centre from the upper, lateral, and lower angles. It is by the persistence and exaggeration of the two fissures in the median line that these hernial protrusions occur so often in the mesial part of the occipital bone. The upper fissure is the last to close; the lower, or that below the occipital protuberance, is almost obliterated at birth. Hernia does not seem, however, to be more common above than below the occipital eminence. In the museum of St. Thomas's Hospital there are two specimens of meningocele, about the size of a walnut, which each communicate with the cranial cavity by means of an oval foramen nine lines in length, situated below the occipital eminence; and one specimen of encephalocele, about the size of an orange, containing part of the cerebellum, and communicating with the cranial cavity by means of a foramen of similar dimensions and relations. The continuity of the lower fissure with the foramen magnum may explain the frequency of hernia below the occipital protuberance, for in many instances this fissure opens out to form with the foramen a huge opening, bounded behind and laterally by the rudimentary exoccipital and supra-occipital elements of the occipital bone. Through this opening the cerebellum commonly passes out into the cavity of the protrusion.

These tumours when large have the skin tightly stretched over them, are of a pink or bluish colour, and, if fluid, readily transmit light. They may or may not be pedunculated; and the tension of any individual tumour may be so great as to interfere with the discovery of the bony margins of the opening in the skull. The same difficulty will be experienced when much solid matter is present. When the tumour is small, it may be reducible by gentle manipulation; but pressure is very apt to set up signs of cerebral disturbance. This fact is of the greatest importance in the diagnosis between the various forms of congenital tumour occurring in this region—between

meningocele and encephalocele on the one hand, and large subcutaneous nævus and dermoid cyst, with or without involvement of the bony vault, on the other, especially when these tumours occur exactly in the median line. It may be noted that nævi and dermoid cysts occasionally make their first appearance a few days after birth. The pulsation of an encephalocele is synchronous with the pulse in the arteries, and clenches the diagnosis of this variety of hernia. Pulsation may, however, also occur in the case of simple meningocele, when there is a large communication between the cavity of the cranium and the cavity of the protrusion. In rare cases, the dura mater is exposed in whole or part without a covering of skin, or there is an ulcerated surface over the centre of the tumour indicating that the dorsal laminæ have not completely closed, so that no epiblast is present from which skin could be produced at the ulcerated spot.

The excess of cerebro-spinal fluid is contained in the expanded subarachnoid space, or in the dilated ventricle, or more commonly occupies both situations. Hydrocephalus externa never exists as an independent affection, but may occur from rupture of hydrocephalic ventricles or as a consequence of large arachnoid hæmorrhage, &c. In ordinary hydrocephalus (hydrocephalus interna) the fluid is limited to the dilated ventricular cavities, and its increase in quantity is intimately dependent upon an inflammatory condition of the lining membrane of the ventricles, which are generally imperfectly developed. Possibly also there is some connection between excess of ventricular fluid and the presence of tubercles or other tumours, which either mechanically interfere with the passage of blood along the veins of Galen, or obstruct the foramina in the pia-matral expansion covering in the lower part of the fourth ventricle, whereby is inaugurated a disturbance of pressure equilibrium within and without the brain. In cases of meningocele and hydrencephalocele, the common association of an excess of fluid in the ventricles with an excess of fluid in the subarachnoid space points to the fact of these conditions originating from one common cause.

When a meningocele is small, the *diagnosis* may generally be cleared up by attention to the following points:—1. The attachment of the tumour to the bone, and its position in the median line. 2. Its congenital nature. 3. Its fluid character—the tension of the cyst increasing during crying, coughing, and other expiratory acts.

4. Cerebral pulsation may or may not be present. 5. The hernia may be partially or wholly reducible, with or without the production of cerebral symptoms. 6. Palpation of the deficiency in the wall of the skull.

Cephalhæmatoma, or a collection of blood between the pericranium and bone, takes place usually over one of the parietal bones. It is limited to one bone by the union of bone and pericranium in the neighbourhood of the sutures, and disappears a short time after birth. A meningocele of the parietal region is rare. Cases have been published of simple fracture of the skull, generally of the parietal bone, in infants, followed by *pulsating tumour*. A cephalhæmatoma forms immediately after the injury, but, the brain membranes being torn as well as the brain-case fractured, cerebro-spinal fluid, and sometimes brain-matter, passes through the rent into the cavity of the blood tumour. Any interval from forty-eight hours to many days may elapse between the formation of the typical cephalhæmatoma and its assumption of pulsatile qualities. The wall of the original blood-tumour becomes in fact the sac of a meningocele or encephalocoele, which must be treated on the same principles as the congenital variety, but could hardly be mistaken for the latter unless the injury were to happen immediately after birth.

A *dermoid cyst* of the scalp is immovable, tense, non-pulsating, fluctuating, not changing with respiratory movements, and occurs most frequently near the outer angle of the orbit. The diagnosis presents, in rare cases, insuperable difficulties, see the interesting case published by Mr. Arnott in the *Pathological Trans.*, vol. xxv.

A *subcutaneous nævus* has no definite margin, increases in size during expiratory efforts, has a doughy, worm-like feel, imparts a bluish tint to the skin over it, is not perfectly fixed, and is not infrequently placed over one or other of the fontanelles.

An *Encephalocoele* appears generally as a small lobulated globular or oval tumour, which pulsates synchronously with the arteries. Mr. Gould has narrated a case, in which pulsation was not evident until the tumour had been partially reduced. Pulsation may not be present; therefore, absence of pulsation must not be relied upon as indicative of the absence of brain-matter in the sac of the hernia. The brain-substance in the tumour can be easily palpated through a layer of fluid. If the sac is very large, and has a broad base, the tumour is always a hydrencephalocoele, and is associated with great deficiency of the bony boundary

of the cranial cavity. In other cases, huge pedunculated sacs may be attached to the occipital or frontal regions, and contain more or less of the proper contents of the cranium. Associated with meningocele and encephalocoele may be other malformations, as hare-lip, cleft-palate, talipes calcaneus, spina bifida either affecting a portion or the whole length of the spinal column, a permanent bulbus arteriosus, as in a remarkable case placed on record by Mr. Heath, or indeed any other condition due to an arrest of the developmental processes.

Prognosis.—These malformations when large may seriously impede delivery, may interfere entirely with the life of the child, or make its prolonged existence improbable or impossible.

Treatment.—If the hernia were small, and the opening in the skull of corresponding size, it might be possible to keep it reduced so that, as the bones ossified, a cure would result. Cases have been recorded in which iodine injection, ligature of the pedicle, or even slicing off the tumour, has been more or less successfully practised. The effect likely to ensue from ligature of the pedicle can, of course, be determined by temporary compression of the neck of the sac. None of these methods are warranted by what we know of the pathology of the disease. Non-interference is the golden rule, except when the tumour is rapidly increasing in size and the life of the patient is in great jeopardy. Under these circumstances it is justifiable to resort to the operation of tapping. In a large hydrencephalocoele of the vertex, seen by the writer some years ago, Sir W. MacCormiac tapped the tumour by means of a capillary trocar connected with a very long and fine tube—gentle pressure and support meanwhile being adjusted to the head. The patient was seven years old, lived for twenty days after the operation, and then died in convulsions. Unfortunately, it is just in those cases in which it is justifiable to interfere that least can be expected from surgical operation. When a peduncle is present, and the tumour is a simple meningocele, the case might terminate happily by the recovery of the child after accidental blocking and sloughing of the peduncle. Operative interference of any sort is out of the question in cases of encephalocoele. The cure of certain meningoceles may, however, be attempted by means of the injection of Morton's fluid, which is employed with such success in the treatment of spina bifida; those cases are most likely to be successfully treated in this way which are of medium size and

pedunculated. Lately, a case has been reported as cured by the injection of Morton's fluid into the cyst-wall, or rather externally to the cyst-wall. The mental condition of the child would have an important bearing on the answer to the question whether an operation was advisable. The almost constant co-existence of hydrocephalus or malformation of the brain with hernia of the contents of the skull, renders futile, as a rule, any attempt at treatment. The best and often the only thing the surgeon can do is, by suitable means, to protect the protrusion from pressure or injury. *See SPINA BIFIDA.*

CHARLES A. BALLANCE.

MENTAGRA. *See* SYCOSIS.

METASTASIS.—By metastasis is generally understood the subsidence or disappearance of inflammation in one situation, with its coincident onset at another.

The morbid states in which it is best exemplified are—(1) pyæmia, (2) gonorrhœa, (3) gout, (4) mumps. In pyæmia and gonorrhœa the disease is primarily local; in gout it is at first general, with subsequent local expression; whilst in mumps there is some doubt whether the initial infection consists in a contamination of the blood or of the parotid glands. Many theories have been advanced to account for the phenomena in question—some fanciful, others well-grounded.

With regard to *pyæmia*, it may be stated with confidence that there are several methods by which metastasis is established. (1) A large number of the so-called 'multiple circumscribed abscesses' beyond all doubt owe their origin to embolic infarction. Portions of disintegrated venous thrombi, on being detached, are swept along by the blood current until they arrive in vessels too small to allow of their transit. The septic nature of these thrombi is incompatible with resolution of the inflammation; purulent softening is certain if the patient survives sufficiently long for its development. (2) The decomposed products of the primary local phlegmon are conveyed by the lymph channels, until they meet with some mechanical obstacle to their passage, and thus a concentration of the poison is effected; or, without this hindrance, they light on tissues already diseased or predisposed to inflammation, which then 'become acutely affected as a result of the general febrile disturbance.' In some instances, the lymphatic tracts connecting the primary and secondary foci show no naked-eye signs of reaction to the irritant that has traversed

them, but as a rule the reverse obtains, especially when the superficial vessels are involved—e.g. in a poisoned wound of the skin with consequent bubo. (3) Microscopical examination has shown that, in the true infective processes, minute organisms—cocci—multiply with great rapidity in the lymphatics and even in the blood capillaries, which become blocked with the accumulated growth. The vital activity of these bodies varies with the soil in which they vegetate. In some parts it is feeble and transient, in others it is marked and long-abiding. Hence the variation in the result, and the explanation of distant suppurative centres connected by a continuous chain of vegetation. (4) The 'secondary abscesses' may depend upon a general blood-infection, and not stand in *immediate* causal relation to the primary lesion. Of this nature are the diffuse metastases met with in the lungs, joints, and connective tissue in some cases of septicæmia—septic infection. (5) Prior to the enunciation and proof of the foregoing ways and means of metastasis, it was the custom to suppose the incidence of the secondary change to be largely due to the reflex action of the nervous system; an explanation at once imaginary and insufficient, and, as is now known, in most, if not in all, cases demonstrably contrary to fact.

What has been said respecting general pyæmia applies in much the same manner to *gonorrhœa*. At first sight, it seems somewhat curious that inflammation of the epididymis and testicle should follow acute purulent urethritis, after so long an interval has elapsed from the original inoculation; but it must be borne in mind that it takes some time for the inflammatory action to spread along the lymphatics from the urethra to the testicle, and this is one mode in which the metastasis is effected. Gonorrhœal epididymitis or orchitis, pathologically considered, is, in the writer's opinion, primarily and essentially a lymphangitis. On the other hand, the infection may be conveyed by the spermatic tract itself, and this is probably the case when the vas deferens and epididymis are much swollen and indurated, with but little thickening of the cord. *Gonorrhœal rheumatism* is generally taken to be a mild form of pyæmia in subjects predisposed to the action of the poison. The fact that a specific 'coccus' is supposed to be always present in the urethral discharge lends weight to this theory.

The metastases in *gout*—as, e.g., when severe stomachic derangement suddenly supervenes on the equally rapid subsidence of an attack of arthritis—are either merely a

series of phenomena having no causal relation one with another, or, what seems not unlikely, the materies morbi of gout is re-absorbed from the articular structures to act upon the tissue or organ next in order of vulnerability.

Metastatic orchitis as a complication of *mumps* is relatively more common in adults than in children, a fact explained probably by the greater physiological activity of the testicular epithelium in mature life. The specific poison selects first the parotid glands; and secondly, though with much less frequency, and at a later period of the affection, the testicle, for its local development. It is curious that two organs differing so widely in many respects should be attacked by the same agent of disease. It will be remembered that enchondroma has a like proclivity for these glands, and here also there is no obvious explanation of the association.

AUGUSTUS J. PEPPER.

MICROCOCCLUS.—A round or oval micro-organism belonging to the class of SCHIZOMYCETES. The term coccus, applied to spherical organisms, has sometimes the prefix mega (*μεγα*, great) to denote a larger variety (Billroth), so that there are two divisions of the round micro-organisms recognised—viz. megacoccus and micrococcus. These round or oval organisms are found in putrid animal liquids, and in some diseases, as below; for their causal relation to which. See SEPTIC DISEASES, Classification and Etiology of.

As regards their personal life, they grow by fission, so as often to form chains of from two to several hundred, while in rarer cases they are grouped into fours or more, like sarcinæ, and they multiply by simple fission of their protoplasm. Micrococci cannot resist heat like the spore-forming organisms; consequently it is more than probable that no coccus possesses in any degree the property of spores.

Sapric M.—*M. sapricus*.—Micrococci of various sizes are found in almost all dead putrefying tissue. Thus they are found in the necrotic foci of pyæmia, and always in the pus of acute abscesses, and in most decomposing albuminoids.

Pathogenic M.—*M. erysipelatosus*.—A micrococcus is now definitely proved to be intimately connected with the causation of erysipelas. It has been cultivated by Fehleisen, who found the period of incubation in the human being was about twenty-four hours on the average. See ERYSIPELAS.

M. septicus, although not so definitely proved (like that of erysipelas) to be an active carrier of infection, has been found so consistently in pyæmic foci as to deserve a prominent place in this list. It is also found in decomposing wounds, growing on the surface of the granulation-tissue.

M. of acute necrosis and osteomyelitis. In acute necrosis and osteomyelitis this micrococcus has often been observed. When cultivated, it forms beautiful orange masses. Inoculated into animals, it produces ordinary septicæmia, unless a bone has been previously injured, when acute osteomyelitis is set up, with abscesses in the lungs, &c., just as in the acute necrosis of man.

M. endocarditicus.—In ulcerative endocarditis, micrococci are always to be seen in the organisms, on the valves, and in the infarcts in the different organs.

M. bombycis, a large coccus organism which causes death by mechanical mycosis, &c.

M. gonorrhœæ.—The micrococcus known for some time to be present in gonorrhœa has been cultivated, and, by inoculation of the growth obtained, been shown to probably produce the disease.

M. variolæ, the organism of small-pox, is, so far as is known, the probable cause of the pustules in their early stages.

M. vacciniæ, a micrococcus found in healthy vaccine lymph, is credited with being the cause of vaccinia.

M. puerperalis.—In puerperal fever a micrococcus has been discovered in the foci of disease, exactly like the organism of pyæmia.

M. nephriticus.—In suppurative interstitial nephritis, secondary to septic disease of the lower urinary tract. Micrococci are found in the tubules of the kidney, and are supposed to have gained access to that organ by growing in the stagnant residual urine and mucus in the bladder and ureter.

VICTOR HORSLEY.

MICTURITION, Disorders of. See INCONTINENCE OF URINE; RETENTION OF URINE; PROSTATE, Diseases of the; PROSTATIC HYPERTROPHY; STRICTURE OF THE URETHRA.

MILIUM.—*Definition*.—A collection of sebum distending a sebaceous gland, but without an external opening.

Symptoms.—Milium consists of a small white swelling under the epidermis, occurring in the same parts, and due to the same causes as COMEDONES. There is, however, no external opening, as the matter is retained in the sebaceous gland, and does not pass into the hair-follicle.

Diagnosis.—Miliun may be mistaken for xanthoma tuberosum and for molluscum contagiosum. An incision into the little tumour will suffice to distinguish it from the former; as, in miliun, the sebaceous matter will be easily forced through the outlet, whereas in xanthoma nothing will escape but a trace of blood, as the tumour is composed of connective tissue, and is therefore solid. Moreover, in xanthoma the appearance is yellower than is the case in miliun. It may be diagnosed from molluscum contagiosum by the central depression characteristic of that disease.

Treatment.—Careful incision into the tumour, removal of its contents, and scraping or scarifying its lining membrane. To prevent miliun forming, care should be taken to wash the skin frequently with soap and hot water. Constitutional remedies must be resorted to whenever there is any functional derangement or general debility.

MALCOLM MORRIS.

MILK-CYST. See GALACTOCELE.

MINER'S ELBOW. See BURSEÆ, Affections of.

MOLE (*Nævus pigmentosus*).—A circumscribed hypertrophy of the skin, with much small-cell infiltration, in the form usually of a papule or tubercle varying in size from a millet-seed to a hazel-nut, but frequently much larger. In some cases the surface of a mole is smooth; in others it is partially concealed by a growth of hair (*nævus pilosus*). The larger and coarser varieties of mole are usually congenital; the smaller are not commonly observed until after the age of infancy and early childhood has passed. Congenital moles, as a rule, grow only in proportion to the growth of the body; the non-congenital usually increase in size for a time and then cease growing. In a small minority of cases, and under quite unknown conditions, a mole becomes the starting-point of melanotic sarcoma, or (very rarely) carcinoma.

Treatment.—With the exception of the considerations involved in the last-mentioned circumstance, which render advisable the removal of any mole that attracts attention by its growth or is in a situation where it may be irritated, treatment is necessary only when, from its situation, as on the face, it causes a deformity which a patient is anxious to be rid of. The treatment of quite small moles is very simple. They are best destroyed by the application of strong nitric acid; care being taken not

to apply the caustic too freely. For the removal of larger moles, say those from the size of a pea to a horse-bean, a smaller scar will probably be left after removal by the knife or a Volkmann's spoon than by caustic; but great caution should be exercised when the disease encroaches on the thin skin in the neighbourhood of the eyelids, on account of the liability to ectropion from the contraction of scar-tissue in this region. In the case of large moles, say from half an inch to an inch or more in length, the surgeon will do best by removing a portion at a time; the result of the operation being taken as a guide to future proceedings. Either the knife or caustic may be used; the former usually causing less scar than the latter. But it is impossible to lay down a strict rule for all cases.

In the case of very large moles—too large to permit the removal of the whole thickness of the skin at once—a good deal can be done by removing with a sharp scalpel or Volkmann's spoon the *surface* of the skin, only a part of the thickness of the corium or true skin being removed, and no part of the subcutaneous tissue being exposed. The wound should then be covered with a piece of gutta-percha tissue as a first dressing, and after a day or two allowed to scab. By these means, partly by the knife and partly by strong nitric acid, the writer was enabled to remove successfully, and without any subsequent contraction of the scar, a large hairy mole which occupied half the forehead.

W. MORRANT BAKER.

MOLLITIES OSSIUM. See OSTEO-MALACIA.

MOLLUSCUM CONTAGIOSUM (*Synon.* Epithelioma molluscum—Virchow; Acne varioliformis—French authors).—*Definition.*—A chronic disease of the skin, characterised by the development of small tumours, rarely exceeding the size of a pea.

Cause.—This is not certainly known; lately it has been attributed to the presence of a vegetable parasite. There has been much discussion as to the contagiousness of the disease. In America and on the Continent, where the disease is much rarer, it is scarcely believed in, but in this country its contagious nature is almost universally accepted, this belief being based upon such clinical facts as the following:—

1. The frequent simultaneous appearance of the disease on the face of an infant and the breast of a nursing mother.

2. Its occurrence on contiguous surfaces—e.g. the insides of the thighs.

8. Its liability to affect more than one pupil in a school or one member of a family, at the same time.

It must be confessed, however, that inoculation experiments are rarely successful; probably warmth and moisture, with continued friction, are the conditions most favourable for its inoculation.

Pathology.—If a small molluscum tumour be examined microscopically, it will be found to consist of cells packed together in lobular masses, bounded and separated by fibrous tissue. The cells composing the lobules may be roughly divided into two kinds—(1) those at the periphery, closely packed, having large oval nuclei, and corresponding in appearance to the normal cells of the rete mucosum; (2) those towards the centre of the lobule, which are large, ovoid, vitreous-looking bodies, closely placed or more loosely arranged in a reticulum, often of a granular aspect. These are the molluscum bodies, concerning the composition and nature of which there is still much controversy. In vertical sections of minute commencing lesions it has been shown that the peripheral cells of the new growth are continuous or closely associated with the Malpighian layer of the skin, or with that inversion of it which constitutes the outer root-sheath of the hair-follicle. The molluscum bodies are, probably, the result of retrograde changes in the cells concerned in the formation of the hair-structure.

Symptoms.—The lesions develop slowly, taking weeks or months to attain the size of a pea, which they rarely exceed; they commonly appear as flattened pinkish-white tumours, possessing on the infant's skin a peculiar greasy, semi-translucent appearance. In every lesion there is distinguishable, from its very commencement, a central pit or depression (umbilication), probably the widened mouth of the hair-follicle from which it started. This central depression, together with the early flat sessile appearance of the lesions, has suggested their likeness to pearl shirt-buttons. As the tumours increase in size, they overhang their bases and so become pedunculated, but, unlike the *molluscum fibrosum* tumour, they rarely become pendulous. Two or more tumours are liable to coalesce and merge into one larger tumour, which in this case presents more than one orifice. Large tumours are apt to inflame and suppurate, but this may happen to any tumour that is irritated by friction, &c. On squeezing the tumours, a thick, gruel-like fluid can be made to exude from the orifice; sometimes the fluid is thin and milk-like,

and issues in a jet on pressure. If the orifice of a tumour be slightly enlarged with the point of a lancet, and firm pressure be made on either side of its base, there can be forced out or enucleated a pinkish mass which to the naked eye has a minutely lobular appearance not unlike gland-tissue. The tumours are generally few in number and occur in young subjects, but isolated cases are on record in which hundreds of tumours have been present on adults. No pain or itching is complained of.

Diagnosis.—A well-marked example of the disease is not liable to be mistaken for any other affection. Sometimes difficulty arises when attention is drawn to a single suppurating tumour, the special appearances being masked by the inflammation; the probable existence of other molluscum lesions, perhaps so minute that they have at first escaped notice, will help the diagnosis.

Treatment.—Only local treatment is of use. The tumours may be removed by enlarging their orifices and enucleating their contents. If there is much trouble in completely freeing the capsule, the contents may be removed with a small Volkmann's spoon; the large tumours will probably require such treatment. The base of the capsule may be touched with nitrate of silver, to prevent bleeding. The lesions rarely recur.

ALFRED SANGSTER.

MOLLUSCUM FIBROSUM.—*Definition.*—Soft tumours of the skin, due to hyperplasia of the subcutaneous tissue and deep layer of the corium.

Etiology.—The only known cause is congenital predisposition. The tumours occur in both fair and dark races in both sexes, and are seen at all ages, though they nearly always begin in early childhood, and some in the first few months of life, being probably often congenital, but too small to attract notice. The dermatolytic tumours may, however, be acquired in later life, and there are also tumours, of a very similar character to those of childhood, which develop in elderly people, especially between the shoulders and on the face, but they are never numerous. In a considerable proportion of those in whom the tumours commence in early childhood, it has been noted that they have been stunted in both their mental and physical development.

Pathology.—Nothing is certainly known of the pathology of these tumours, beyond the fact of their being immediately due to a hyperplasia of the connective tissue of

either the deep part of the corium or subcutaneous tissue, or both, while some tumours seem to take their origin from the connective tissue round the hair-follicles. In the diffuse or dermatolytic cases, the presumption is in favour of this hyperplasia being due to an obstruction to the lymph-flow in the superficial lymphatics, but we are entirely ignorant of the way in which it is produced. This theory and many points in its anatomy bring this disease into pathological relationship with elephantiasis Arabum, though the clinical differences are obvious.

Anatomy.—On section of a medium-sized tumour it is found to consist of more or less perfect fibrous tissue, from which a small quantity of clear yellow fluid can be expressed. The fibrous tissue is coarsest and best developed at the base, while in the centre it is loose and gelatinous, and at the periphery fine and delicate. The degree of development of the fibrous tissue is in proportion to the age and size of the tumour; so that in a large tumour there will be very little gelatinous tissue, while a smaller one may consist entirely of it. In all, the papillary layer of the corium and the epidermis are unchanged. Cells with large nuclei are scattered singly, in foci, or in strata between the layers of connective tissue, and are most abundant in the young, and sparse in the old, tumours. The vascular supply is derived from large vessels, which enter at the base and are distributed in fine capillaries at the periphery.

Varieties.—There are the following varieties:—1. Multiple, small, soft tumours, in which the surface of the skin is normal. 2. Dermatolytic tumours, with small tumours like the first variety. 3. Dermatolytic tumours without other tumours.

Variety 1.—The tumours are roundish and soft for the most part, though they may be firm in places, and when pinched up, the contents can be rolled between the fingers. The skin over them is either tense or lax, smooth and of normal colour, except sometimes from vascularity, and it is not uncommon to find the plugged orifice of a sebaceous gland in the centre of a small tumour. The tumours vary in size from a pin's head to a hen's egg, though the majority are not larger than a walnut; some are sessile or even deep in the skin, others pedunculated. They come most frequently and abundantly on the trunk, next on the occiput and the rest of the head, face, and limbs; but they are rare on the palms and soles, where, if pre-

sent, they get flattened by pressure. Occasionally the mucous membranes become involved, especially the lips, gums, and hard palate. The tumours gradually increase in number and size, but do not tend to shorten life, and are only inconvenient from their size, position, and numbers, and, though sometimes few, are often present in hundreds, and even thousands. Occasionally, when the growth is unusually rapid, they get tense and red, excoriate, or even ulcerate, and slough off from the vessels being stretched and occluded.

Variety 2.—In the dermatolytic cases, besides the tumours already described, there are others much larger, often weighing many pounds; they have a broad attachment, consisting of lax pendulous masses, which may be in folds like a coachman's cape, and feel like masses of skin and fat. These tumours spring most frequently from the occipital region, the side of the neck, flanks, buttocks, thighs, and sometimes from some parts of the face. They may reach to an enormous size, and, when they occur without the small tumours, constitute Variety 3, which is placed separately, because, whilst the other varieties begin in early childhood, these may be acquired. The tumours are often even more diffuse than in the last kind, and, in a case under the care of the writer, the enormous pendulous folds depended like flounces from the buttocks and thighs, in consequence of prolonged suppuration in the buttocks produced by a fall. In a few rare congenital cases, the skin has been very lax when pulled out, but without any hyperplasia, and retracted to the normal degree when the traction ceased; but this is evidently a different condition altogether.

Diagnosis.—When there are multiple soft, sessile, or pedunculated, roundish tumours with the skin over them normal, there can scarcely be any difficulty in the diagnosis. Multiple fatty tumours are most like them, but they are flatter, lobulated, and do not project globosely above the surface, in the way some of the molluscum tumours are sure to do. When the tumours are single or few, the diagnosis from soft moles would be made by the fact of the moles having been congenital, and not having grown materially from birth. They may resemble sebaceous cysts, but though a large comedo is common in the molluscum tumour, on pressure nothing but the comedo can be expressed, while nearly or quite the whole of the contents can be squeezed out from the sebaceous cyst.

Prognosis.—The tumours tend to increase in number and size, and although occasionally the contents of a small one may be absorbed, it makes no practical difference to the disease as a whole. They may be inconvenient, but are never dangerous to life.

Treatment.—Where any one tumour is inconveniently placed, or where there are only a few, if pedunculated they may be removed by ligature, the galvanic cautery or écraseur, and if sessile excised. Large dermatolytic tumours have also been successfully removed in several instances, but the removal must be complete, partial excision having been followed by regrowth.

H. RADCLIFFE CROCKER.

MORPHŒA. See **SCLERODERMA**.

MORTIFICATION. See **GANGRENE**.

MOUTH. See **PALATE**, Affections of the; **RANULA**; **STOMATITIS**.

MOVABLE KIDNEY is a condition in which the organ has lost its usual attachments in the perinephral fat, and glides about a varying area attached only by its vessels and ureter. In some cases, it slips about behind the anterior peritoneal covering; in others, it has gradually come forward until it has drawn out for itself a sac of serous membrane, covering both its surfaces, and gathered in round the vessels of the hilus so as to form a mesonephron. For the latter condition, said to be congenital as a rule, the term 'floating kidney' has been suggested, to distinguish it from the commoner 'movable kidney.' Both conditions are not so infrequent as is supposed. Thus, out of 5,500 patients, examined in a German hospital specially on this point, about 1 in 250 had movable kidney. Among women it is found much more frequently than among men, and this fact, perhaps, furnishes us with a clue to its causation; the latter, however, still seems somewhat obscure. But it is significantly frequent between the ages of twenty-five and forty in females, and this being the most active child-bearing period, it seems not improbable that the changes taking place during gestation in the abdomen, and more particularly after parturition, when the parietes and internal organs are relieved from a great strain, may play an important part in the displacement of the organ. Tight-lacing is also supposed to explain its greater frequency among women. This may also be one of the causes why it is more frequent on the right side than on the left, for on the right it is less protected

against the constriction of the girdle or stays than on the left, where it is more or less covered by the stomach and spleen. But, in many cases, the occurrence of movable kidney can be traced to some violence, such as a fall or blow upon the side; or to hard riding, which, having once shaken the kidney loose from its attachments, has never permitted it to recover itself again.

The *symptoms* are usually not very marked—indeed, the condition is often discovered accidentally where none have ever been present. But, in some cases, there can be no doubt that very severe suffering is caused by the movements of the organ, and, most probably, by the drag upon the pedicle. Among the symptoms in severe cases may be mentioned dragging, sickening pain in the loins, with nausea and, occasionally, vomiting, diarrhoea or constipation, and frequency of micturition; other less definite sensations are often complained of, such as depression of spirits and general weakness.

The *diagnosis* of the condition is based upon the above symptoms, and on the presence of a movable tumour, of the size of the kidney, somewhere between the normal position of the latter, the umbilicus, and the anterior superior spine of the ilium. This tumour is freely movable in an upward direction or laterally, but not downwards, as the patient stands. It can be easily thrust upwards above the ribs into the normal position of the kidney. If grasped or pressed upon, a dull, sickening pain is complained of.

Treatment is not always called for in these cases. If there be much suffering, however, several means have been found of relieving it. In the first place, rest in the recumbent position is usually temporarily useful, then firm bandaging of the abdomen with a pad placed over the replaced kidney; next, attention to the bowels, and the use of tonics and cold douches, &c.; lastly, stitching the offending organ to the abdominal walls has been tried with benefit. See **NEPHRORAPHY**. Finally, removal of the offending organ has been resorted to in several severe cases, but so far has not been considered a justifiable procedure in this country. In all cases where there is suffering, violent exercise is to be avoided. Occasionally the symptoms are severe and give rise to suspicion of inflammation in the kidney, in which case leeches and hot baths and fomentations should be employed, with the internal use of opium and diaphoretics.

The *prognosis*, in cases where the movements of the organ give decided trouble, is not very favourable as regards the prospect of permanent relief without operation. Once having broken loose from its attachments, the kidney is very unlikely to become fixed again spontaneously. Fortunately, in many cases, the condition causes but little suffering, and is amenable to treatment by rest and palliatives.

A. E. BARKER.

MOXA. See ISSUES.

MUCOUS PATCHES.—The mucous patch, known also as mucous tubercle and mucous plaque, is a very frequent lesion of acquired secondary, and of inherited syphilis, and, in an exaggerated form, has been met with occasionally in tertiary syphilis. As a manifestation of secondary syphilis it occurs early, and is associated with the papular eruption. It is met with usually in a multiple form, and is situated either on mucous membrane, or on thin and moist skin subject to friction or the frequent contact of irritating secretions or foreign material. The favourite situations of crops of mucous patches are the vulva in women, the skin about the anus both in men and women, and the scrotum and scroto-crural fold in men; but especially on the tonsils, on the tongue, and at the labial commissures. The lesion, when developed on a cutaneous surface, presents an oval elevation of a whitish-grey or pink colour, dry on the surface, and surrounded by a zone of red and inflamed skin, from which there is a continuous discharge of thin and very fetid serous fluid. When situated on the mucous membrane of the tonsil and tongue the patch has a smoother surface, is more defined at its margin, is less elevated, and causes less local irritation. When mucous patches, on a cutaneous surface in constant contact with another surface, are frequently irritated by the friction of clothes or by discharges, the patient usually suffers much from itching and sometimes smarting pain; but the lesion, when affecting a mucous surface, causes as a rule but little trouble, and is frequently unnoticed. The mucous patch is often associated with some fissuring and ulceration of the adjacent parts, especially when it occurs at the labial commissures, and when met with in congenital syphilis; and also as the manifestation of advanced syphilis described by Fournier as the 'tertiary syphilitic plaque.'

In dealing with cases of mucous patches, particularly when occurring in infants, it is

very necessary for the surgeon to bear in mind the well-established fact that the discharge from the surface of this lesion is highly contagious.

The *local treatment* of mucous patches, when situated on a cutaneous surface, should consist in attention to cleanliness of the affected region, in one or two applications of solid nitrate of silver or sulphate of copper, and frequent dusting with calomel powder. When situated on a mucous surface, especially in the mouth, the local application of a ten-grain solution of chromic acid (Butlin) will be almost universally attended with a good result.

W. JOHNSON SMITH.

MUSCÆ VOLITANTES. See VITREOUS, Diseases of the.

MUSCLES, Affections of.—**CONTUSION.** Muscles are liable, like other textures of the body, to suffer from contusions or bruises.

Causes.—The principal are blows and kicks, the impact of spent balls in warfare, and splinters from objects struck or blasted; also falling against a firm obstacle, or the fall of some object on the person.

Pathology.—A bruise implies more or less injury to texture, and may vary from a very slight injury, causing pain and stiffness for a few days, to one which may reduce the muscle to pulp and compromise its vitality. In even the simpler cases, however, there is more or less tearing of the fibres, or of their ensheathing sarcolemma, or of the nerves or blood-vessels. This explains the extravasation of blood, and loss of function in the muscle, which generally follow injury, in varying degree. Bruise of muscle is common, though not so much so as one might suppose from the vast extent of muscular covering with which the body is invested. The muscles more liable to suffer are the deltoid, gluteus maximus, those of the lower limb generally, and of the abdomen.

Symptoms.—Pain is of a dull character. There is inability to use the muscle, with increase of pain when the attempt is made. Swelling is present, due to extravasation of blood and effusion of serum. The swelling is deep-seated; that is to say, under the fascia. Ecchymosis may be evident at once, from injury to the superimposed skin. But discoloration from the bruise of the muscle will not appear for some time (days probably), and will then be at some dependent part, from gravitation of the blood. The symptoms which present themselves later are—atrophy from injury to nervous or vascular supply, or both; loss of power from

injury to the fibres or the motor nerves; contraction from the parts being held in a position of relaxation to relieve pain; lastly, inflammation and even abscess may succeed a bruise of muscle.

Diagnosis.—The only difficulty is in cases where the muscle injured lies over a joint, such as the shoulder. The primary swelling and subsequent (occasional) flattening from atrophy and loss of power in the arm, may be supposed to be due to dislocation. Careful examination should, however, enable the surgeon to make out that there is neither dislocation nor fracture in any given case, and thus certainty is reached by a process of exclusion. *See* DISLOCATIONS; FRACTURES; also SHOULDER; HIP, &c.

Treatment.—1. Rest of the muscle and relaxation of it, if possible; 2. Prevention of effusion of blood; 3. Restoration of function to muscle; 4. Prevention of evil results, such as inflammation, contraction, atrophy, &c. The first two indications are best carried out by attention to position and support with a bandage evenly applied over cotton wadding, or by cold, or by anodyne or astringent lotions. Cold may be easily applied by pounded ice in a waterproof bag of any kind, by irrigation, maintained by placing a few threads of worsted hanging from a vessel filled with cold water, or by evaporating lotions. A convenient formula for the latter is *R. Ammon. hydrochlor. ʒj.; Pot. nitratis ʒj.; Aquæ fʒvj. or viij., to which is sometimes added Sp. vini rect. fʒj.* For astringent lotions hazeline, tincture of arnica (1 to 7 of water), or lead and opium (gr. viij. of each to the fʒj.) may be used.

The third and fourth indications should be carried out by early movements, to prevent stiffness and contraction, and the combination of rubbing, kneading, and movement termed 'massage' (*see* MASSAGE). Weakness of the muscle and some pain in using it will continue for a time. Gentle support will often relieve this, along with the douche of hot water at night and cold in the morning. The application of the galvanic current will be necessary should atrophy or paralysis threaten.

In applying electricity to muscle the following rules should be followed:—

If there is simple atrophy without paralysis, this is probably due to want of use, and the Faradic current should be employed to make the muscle contract. If atrophy continue, there may have been some injury to the trophic nerves, in which case the constant current (with massage) may be useful. If the muscle do not answer to the stimulus,

then there has been injury to the motor nerve, in which case the constant current should be employed (occasionally reversing and interrupting it) until some reaction is produced, when the Faradic current should be used. In cases of atrophy and of paralysis the maintenance of the temperature of the part is important, and materially assists recovery.

Acupuncture is sometimes of great service in relieving the painful condition of muscles left after an injury, an ordinary darning-needle being plunged a few times into the substance of the affected muscle with immediate benefit.

STRAIN OF A MUSCLE implies something more than mere stretching—a certain amount of texture gives way. This injury is therefore strictly speaking a minor degree of rupture, and may be considered along with the following affection.

RUPTURE OF MUSCLE is caused by a pulling strain in the long axis of the muscle, contraction of the muscle itself, or both of these together. Separation of muscular fibres from wound or blow may also occur, but this will be considered under other heads. There are certain causes which predispose to muscular rupture, such as contraction, atrophy, and degeneration. Rupture of muscle may occur in tetanus.

Symptoms and Diagnosis.—The patient feels a sudden pain as if the part had been struck. There is weakness or perhaps inability to use the muscle. These symptoms occur when there has been a sudden or forcible flexion or extension of a joint, powerful muscular resistance to some force, or a sudden effort made, as when a person tries to recover himself after slipping. If the muscle injured be in the lower extremity the patient may fall. On examining the part, if the rupture has been extensive, a gap in the muscle is felt, which is more marked when the muscle is in a state of contraction, in which condition there is added a swelling above (on the proximal side of) the gap or hollow. There is subsequent swelling from effusion of blood and serum, which masks the depression; but the gap in the muscle appears again after absorption of the effusion and disappearance of the swelling. Later on there remain only loss of power and atrophy of the muscle, which are in proportion to the amount of injury. Diagnosis should be easy if the foregoing symptoms are well-marked. When these are slight then the case may be considered one of slight rupture or strain.

Treatment.—Rest and relaxation of the muscle, to favour approximation of the torn

fibres. In severe cases, where great weakening or entire loss of power in an important muscle might result, it will be necessary to cut down at the part, and sew together the torn ends with catgut, with strict antiseptic precautions. The resulting uniting medium is connective tissue (at first at any rate); after a time the muscle recovers its power entirely. After the rupture has firmly united, use of the part must be commenced, to prevent contraction, atrophy, &c. If movement is begun or permitted too soon, tearing of the uniting medium may take place, or an abscess may form from the irritation.

WOUNDS OF MUSCLE.—These may be divided into *subcutaneous* and *open*, and into *transverse* and *longitudinal*. Subcutaneous wounds are generally inflicted by the surgeon for the treatment of some deformity. Open wounds may be treated as ordinary wounds of the soft parts (*see* WOUNDS). Should the muscle be cut longitudinally, there will be a tendency for the cut edges to close together and so interfere with drainage; should it be severed transversely, there will be a tendency to gape. In the latter instance stitches should be inserted into the muscle itself, and union of the cut surfaces sought for, as already described in the treatment of *rupture* of muscle.

HERNIA OF MUSCLE may occur where there is a gap in the investing fascia. The displaced muscle may be replaced and retained in position by pressure, as by a bandage. Should reduction or retention be impossible, the part may be cut down upon, the opening in the fascia enlarged and then stitched up after the muscle is returned. Such an operation should of course be performed only under strict antiseptic precautions.

CONTRACTION OF MUSCLE.—This condition may occur from malposition of parts (as in torticollis), but usually is in connection with disease (as of the joints). It may also occur after an injury, as in contraction of the quadriceps in cases of fracture of the patella. If gradual extension and use of the parts is not sufficient to restore function and symmetry, tenotomy (section of the tendon), or myotomy (section of the muscle), may be necessary. The latter operation only need be referred to here. It should be performed *subcutaneously*, and in one of two ways—either by cutting across the muscle completely, and keeping the parts separate till union has taken place at a sufficient length to atone for the previous contraction, or by making a number of V-shaped incisions in the substance of

the muscle, as recommended by Dr. Macewen of Glasgow.

Spasmodic contraction of muscle is due to some nervous affection, and should be treated by tenotomy, myotomy, neurotomy, or nerve-stretching, if internal remedies are not sufficient. *See* TORTICOLLIS, &c.

DISEASES OF MUSCLE.—*Myalgia*, or pain in muscle, may be due to injury, nerve-pressure, inflammation, rheumatism, certain febrile conditions, certain poisons, or neuralgia. The treatment will be to get rid of the cause, and locally to apply anodynes or counter-irritants.

Inflammation of muscle, or Myositis, may result from injuries (as bruise or strain), from hypodermic injections (dirty needles), from rheumatism, or from a poison, such as syphilis or septicæmia.

Symptoms and Diagnosis.—There are the ordinary signs of pain, heat, redness, swelling, and interference with function. It will be possible to locate these in the muscle or muscles affected. Should supuration occur, there will be throbbing, rigors, &c. Myositis is a very painful affection, and pain is much increased on movement. In the rheumatic variety, pressure and rubbing sometimes relieve pain.

Treatment.—Rest, application of cold in the early and acute stage, hot fomentations or poultices when the symptoms are fairly established, and anodyne lotions, of which belladonna with glycerine is one of the best. An abscess should be opened early and with antiseptic precautions, as otherwise it is apt to burrow. If the abscess is deep-seated, the skin and fasciæ only should be cut with a knife, and then a director be thrust through the muscular substance in the direction of the abscess. In this way, excessive bleeding is avoided. If opening is delayed, sloughing of fascia is apt to follow.

Sequelæ.—Organisation of plastic effusion may give rise to fibrous bands, which necessarily interfere with the function of the muscle. An abscess becoming absorbed may give rise to a caseous concretion. Contraction of a muscle may remain for some time after inflammation, to be treated by extension, friction, and use of the parts.

MUSCULAR RHEUMATISM.—The commonest examples are lumbago and pleurodynia, the causes being strains, colds, gonorrhœa, syphilis, and rheumatism. It is supposed to be a subacute inflammatory affection, and is very apt to recur. Treatment: counter-irritation and anti-rheumatic remedies. The writer has found in certain

persons, in whom pleurodynia or lumbago are apt to occur from exposure to cold, that tincture of *Actea racemosa*, in thirty or forty drop doses, repeated every four or six hours, is sometimes beneficial.

SYPHILIS IN MUSCLES.—Syphilis may give rise to myositis, myalgia, contraction, and gummatus infiltration. *See SYPHILIS; GUMMA.*

When gummata occur in muscle, it is generally in the form of hard masses, which give a beaded appearance to the muscle. They tend to soften and break down. They are not very painful, and do not interfere much with the use of the part. They disappear under treatment with potassium iodide and counter-irritation. If left to themselves they tend to suppurate.

HYPERTROPHY OF MUSCLE.—This may be true and simple, from use and increase of vascular supply, or false and due to fatty deposit, or to the so-called pseudo-hypertrophic condition. The tongue is prone to suffer from a hypertrophic condition termed macroglossia, caused by attacks of glossitis, due to lymphoid infiltration, and frequently requiring removal of a portion of the organ. *See MACROGLOSSIA.*

ATROPHY OF MUSCLE.—(1) Simple atrophy may occur from a variety of causes, such as injury, want of use, pressure, injury to a nerve or blood-vessel, ankylosis of a joint, disease of a joint, and lead-poisoning. Treatment must be according to cause, with the use of galvanism, blisters, passive motion, friction, massage, &c.

(2) Atrophy may also occur as a symptom of disease of the nervous system, as in infantile paralysis, progressive muscular atrophy and pseudo-hypertrophic paralysis, which, being medical affections, will not be considered here.

Paralysis in children frequently causes deformities which require, for their treatment, operations. *See CLUB-FOOT; LATERAL SPINAL CURVATURE.* The treatment of atrophy after injury is referred to under Bruise of Muscle.

Degenerations of Muscle.—Fatty degeneration may be due to want of use, improper diet, alcoholic indulgence, or disease. Treatment will be exercise, a properly regulated diet, &c.

Waxy degeneration is found in connection with some fevers, granular after myositis or associated with fatty degeneration. Pigmentary degeneration may be associated with atrophy or the wasting of old age. Calcareous degeneration has been observed in connection with a similar condition of other organs.

OSSIFICATION OF MUSCLE.—This differs from calcareous degeneration in the fact that there is a formation of true bone. The stony hardness of the deposit, along with the interference with the function of the muscle, should make diagnosis comparatively easy. In regard to treatment there is little to say. Blisters are said to relieve pain and check the morbid process.

TRICHINOSIS, affecting the muscles, occurs not infrequently in this country, but is much more common abroad. The disease is shown by the presence in the muscles of numerous whitish specks, each of which, under the microscope, is seen to contain a small worm coiled up in a spiral form. The ingestion of raw or imperfectly cooked flesh, especially that of the pig, as in hams and sausages, is the only known source by which the trichinae find access to the body. Within a few days after the worms are swallowed, they produce eggs, and the embryos when hatched speedily find their way to the muscles, either directly or through the vascular system.

Symptoms.—The patient complains, first, of loss of appetite and prostration, the face also swells; the muscles next become painful, swollen, and contracted; cedema then supervenes. This disease has been mistaken for acute rheumatism, but the absence of joint-implication should be a sufficient guide. No treatment is of any avail.

TUMOURS OF MUSCLE.—These are fibroma, lipoma, enchondroma, osteoma, angioma, cystoma, myxoma, sarcoma, and carcinoma. A. G. MILLER.

MUSCULO-SPIRAL PARALYSIS (Crutch Paralysis, Chair-back Palsy, Drop-wrist).—**Symptoms.**—Loss of power over the supinators of the forearm and extensors of the wrist and hand, in consequence of which the forearm assumes the position of complete pronation; the hand drops loosely forwards on the wrist, the fingers are flexed into the palm and lie over the thumb, which is adducted. Attempts at extension of the hand are followed by some flexion of the first phalanges and extension of the second and third, due to the action of the lumbricales and interossei. A slight amount of supination can be effected with some effort by the biceps, when the forearm is semi-flexed. Extension of the forearm upon the arm will be more or less affected; the higher the nerve-lesion the more complete will the loss of this extension-power be. The onset of the disease may be sudden

or gradual; cases in which it is gradual usually commence with weakness about the hand and wrist, the supinators are then affected, and finally the triceps. There will be loss of sensation over the cutaneous parts supplied by the nerve.

Causes of Sudden Paralysis.—Sharp blows on the musculo-spiral nerve as it winds round the humerus; the palsy from such a cause is usually transient. Division or laceration (1) in direct wounds, (2) by ends of fragments of a fractured humerus, or (3) during removal of sequestra in operations for dead bone; pressure on the nerve by a sharp edge (e.g. back of a chair); laceration of the brachial plexus; cerebral lesion.

Causes of Gradual Paralysis.—Degeneration of nerve after injury; implication of nerve in callus about a fracture of the middle of the humerus; pressure from a crutch; lead-poisoning; syphilis.

Treatment.—In division of the nerve in an open wound, its divided ends should be found and united by suture; the same course should be pursued, if possible, when the nerve is divided in operations for extracting sequestra. In division from simple fracture, the bone may be allowed to unite and then, if the palsy continues, the nerve-ends should be dissected out and brought together with suture. When implicated in callus, the nerve should be cut down upon and freed from the pressure. *See NERVES, Injuries of.*

In crutch and chair-back palsy the recovery is usually spontaneous the cause having been removed, but may be assisted by electricity, 'massage,' and muscle exercise, treatment which may also be useful in the degenerative form. In cases dependent upon lead-poisoning or syphilis, iodide of potassium in 5 to 10 grain doses will usually effect the cure, aided, if necessary, by the mechanical treatment just mentioned.

MYOMA.—Muscular-tissue tumours would be held to be rare, but for the presence of this element in growths whose structure

in the main is composed of other tissues, as the myo-fibromata of the uterus and the myo-adenomata of the prostate. With these composite tumours excepted from the list, comparatively few instances of pure myoma have been described, and they, for the most part, have been found either in the immediate area of the kidneys of very young children or in the walls of the alimentary canal, the gullet perhaps most usually. In speaking of myomata, these are regarded as the true type of muscle-tumours, although the term myoma, when introduced, was intended to distinguish tumours, apparently fibrous but in which flat muscular fibres occur abundantly, from the ordinary fibrous tumours formed solely of connective tissue.

Cause.—The myomata which occur in infants are almost certainly congenital; hence their cause is to be found probably in errors of development. For the myo-fibromata of the uterus, which are the commonest form of these growths, it is sufficient to point out that the two elements of muscle and fibrous tissue mainly constitute the organ, and that during the menstrual period of life the uterus is once a month the seat of active hyperæmia. That this periodic turgescence of the organ is the cause of these tumours, seems evident from the shrivelling which often follows, and may be expected to follow upon, the menopause. Lastly, these tumours seem to be hereditary in the female members of some families.

Pathology.—As has been said already, myomata connected with the kidney form some of the best examples of muscular-tissue tumours. They are usually of firm consistency, yellowish-white in colour and irregular outline; on section, bands of interlacing fibres are seen; under the microscope the fasciculi are seen to be composed of muscular fibres, whilst nodules of fibrous tissue are commonly interspersed.

Symptoms and Diagnosis.—As before removal it would be impossible to distinguish these tumours from fibromata, all that can be said is that they are firm and nodulated, sometimes doubtfully fluctuating. Should, however, a suspicion exist of a tumour being a myoma, the fact could of course, as a matter of interest, be ascertained by teasing out a fragment and microscopically examining its structure.

Treatment.—There are no special circumstances attaching to the treatment of myomata. Whether to perform an operation for their removal or to leave them alone has to be determined upon the general principles of dealing with solid tumours.

MYXŒDEMA. *See* THYROID GLAND, Diseases of the.

MYXOMA.—A new-growth of the connective tissue type, the essential feature of which is a gelatinous material, termed 'mucous tissue.' Tumours of this nature may be quite *simple*, as in nasal mucous polypus; or *complex*, as in myxo-adenoma, myxo-chondroma, or myxo-lipoma. These latter tumours, as a rule, grow either in the salivary and mammary glands or in the areolar subcutaneous tissue; but they are rare, and are of more interest to the pathologist than to the practical surgeon.

Pathology.—Myxoma is usually an affection of the adult period of life. In some complex tumours the myxomatous elements even appear to have been superadded to the original growth, possibly as a degene-

ration of its tissue. Microscopically, a myxoma resembles embryonic fat. It is composed of scattered cells, usually stellate in shape, with very fine connecting fibres widely separated from each other, whilst in the interspaces a fluid like mucus is contained. This fluid exudes freely from the cut surface, and possesses the specific characters of mucus.

Symptoms and Diagnosis.—Myxomata, other than nasal polypi, can scarcely be said to possess such definite features as to enable one to distinguish them from other tumours, whose consistency seems doubtful and suggestive of partial fluidity of contents. An aspiration and examination of the mucoid fluid extracted might enable a diagnosis to be made before operating. After removal, a myxoma may be diagnosed from a colloid growth, which it most resembles, by the fact that the colloid material is for the most part contained within cysts; but still more by the different microscopic characters of their respective cells and by reactions to chemical tests for mucin.

Treatment.—There is nothing in the nature of a myxoma to contraindicate the removal of any tumour thought to be of this character. ALFRED WILLETT.

N

NÆVUS, literally a spot or mole on the body.—This disease is, according to the classification of tumours at the present day, placed among the angiomas or vascular tumours. It is popularly known as mother's-mark or strawberry or raspberry tumour, but it has received almost numberless professional synonyms in various countries.

Causes.—Nævus is generally regarded as a congenital affection, and yet it often first shows itself a month or six weeks after birth. It is popularly supposed to be due to some impression made upon the mind of the mother during pregnancy.

Varieties.—It will be most satisfactory to consider nævi from a clinical point of view, and to divide them into three classes.—(1) those in which the skin is principally involved—the cutaneous; (2) those in which the subcutaneous tissues are principally implicated—the subcutaneous; and (3) those in which the skin and subcu-

taneous structures are simultaneously involved.

Situations.—Nævi are generally supposed to be met with most frequently on the head and face, and no doubt these are common situations; but this conclusion may be fallacious, inasmuch as, being more exposed to view, they are apt to attract more than ordinary attention. It is alleged that they are more commonly met with in girls than in boys, and they do not seem to interfere with the general health. Nævi occur in all parts of the body, not only on the skin, but also on mucous surfaces, as the conjunctiva, extending even to the retina. They are found in the mouth, inside the cheek, on the hard palate and gums, on the tongue, fauces, and pharynx, and in the cavities of the nose and ear; and, further, the vascular structure has been noticed within as well as without the skull, the capillaries of the dura mater and scalp being simultaneously involved.

These vascular growths are also not uncommonly met with on the pudenda, and one case is recorded of nævus of the scrotum.

Symptoms and Diagnosis.—With regard to the *cutaneous* variety, there is usually no difficulty in arriving at a correct diagnosis. The nævus presents itself as a crimson spot of variable shape and size. It is generally circular, not uncommonly having an irregular, leaf-like edge. In some cases it is smooth on the surface; in others it has a granular appearance not unlike the surface of a raspberry, hence its popular title, raspberry-mark. Its progress is comparatively slow, owing to the resisting nature of the skin. It may or may not be raised above the level of the skin, and it often has at its circumference a scarlet appearance whilst the centre presents a cicatricial aspect, having a white glistening surface with small vessels meandering in all directions. Pressure with the finger causes the colour to fade or almost disappear, but the instant the pressure is relaxed the growth re-assumes its vivid hue. There is, as a rule, no marked pulsation in this variety, but the tumour may become excessively turgid when the child cries. There is a great disposition in this variety for the nævus to remain stationary, and ultimately to disappear altogether without operative interference.

The diagnosis of the *subcutaneous* variety is not always so easy, and the difficulty depends to some extent upon its depth from the cutaneous surface, as well as upon the thickness of the integument covering it. Surgeons of repute have committed and acknowledged errors in diagnosing these cases: thus an instance is recorded in which a child had a small tumour situated at the inner angle of the right orbit, presenting apparently all the characters of a subcutaneous nævus. Threads were passed through the tumour with the view of effecting a cure. Cerebral symptoms came on soon after the operation, and the child died. At the post-mortem, an encephalocele was found passing through the suture between the ethmoid and frontal bones. Again, an operation was undertaken with the view of removing a supposed atheromatous tumour of the cheek. The growth turned out to be a vascular tumour, and as the hæmorrhage was smart it was removed by ligature. Erectile tumours have also been mistaken for enlarged glands, and a meningocoele at the anterior fontanelle for nævus.

The subcutaneous nævus has generally the following characters:—The skin is thinned and transparent, and through it may be discerned a bluish patch of variable hue, having an oval or globular outline with or without definite limits. Sometimes, probably arising from position or from extreme thickness of the skin, no change of colour is noticeable, and the patient is brought to the surgeon because there is a slight fulness or swelling of the part, which, if it be on the face, occasions a slight or well-marked deformity. The size of course, varies, but on manipulation the growth has a doughy, soft, boggy feel, not unlike a bag of earthworms or even a piece of fat. Sometimes it has a granular or shotlike feel to the touch. Slight pressure diminishes the size of the tumour, but the growth refills steadily and surely as the pressure is withdrawn. There is little, if any, decided pulsation, and if present it is of a slow, indolent character.

The *mixed* form of nævus partakes, as may be supposed, of the characters of the two varieties just described. The skin itself is often disproportionately affected; there is frequently only a small crimson patch involving the skin, whilst the subcutaneous structures are implicated to a far greater extent than might at first sight be supposed; thus, in one instance the superficial redness was scarcely the size of a threepenny-piece, whereas the deep swelling was fully four inches in diameter.

Pathology and Progress.—Pathologically, a nævus may be described as a tumour consisting of blood-vessels communicating in various degrees, and united more or less by connective tissue, and matted together in a mass in the subcutaneous or some other tissue. Two classes of nævi are described. 1. The simple *angeiomata*, in which the new vessels are exactly like the normal capillaries or arteries and veins. These vessels may be newly formed, but, in many instances, they appear to be the original vessels enlarged to a considerable extent. 2. The cavernous *angeiomata*, in which there is a structure closely resembling the corpus cavernosum of the penis. Here there are a number of alveolar spaces, sometimes much larger than those in true erectile tissue, which are distended with blood supplied by numerous arteries, the fluid circulating feebly through them. Other observers believe that nævi commence in the capillary network of vessels which normally surround the hair-follicles.

Nævi make variable progress: the strictly cutaneous form either remain stationary, or disappear spontaneously without any interference on the part of the surgeon; in the subcutaneous and mixed forms an operation of some kind is generally called for. But these, again, may remain stationary, or they may suppurate and thus get disintegrated; or they may undergo fatty degeneration, when they are known as nævoid lipomata; or they may undergo cystic degeneration, the cysts being filled with a clear, sanguinolent fluid.

Treatment.—There is scarcely any limit to the number of methods that have been devised for the cure of nævus, and perhaps it is well that the surgeon should have a choice, because each case must be judged on its own merits; and the treatment will necessarily vary with the nature of the case, depending upon the situation and character of the morbid growth. The main object is to arrest the growth, so as to leave a non-vascular cicatrix in place of the nævoid tissue. As already stated, surgical interference is not always required; without any assignable reason the vascular spot sometimes disappears spontaneously, or its disappearance seems to be induced by some trifling cause. Such cases are, however, rare, and more frequently the surgeon is compelled to have recourse to operative measures of some kind.

1. *Compression.*—This plan of treatment at first sight seems inviting, but it is obvious that the morbid growth must be so placed as to ensure a firm *point d'appui*. Abernethy treated a severe case of nævus of the arm by applying a many-tailed bandage of sticking-plaster to the part. A roller was applied over the plaster and kept wet, so that (1) equable pressure was obtained, and (2) reduction of temperature effected. The cure, which was, however, only partial, took six months.

It has been alleged that even the pressure of the child's clothes has arrested the growth. Collodion and styptic colloid applied thickly have certainly a marked effect in reducing the size of nævi. An astringent effect may also be produced by a saturated solution of alum, either in rose-water or glycerine. The ether spray has been employed, and also a method of subcutaneous rupture, in which the nævi is rapidly squeezed so as to break up the vessels when full.

2. *External applications* may be used to excite either adhesive or superficial suppurative inflammation. Dieffenbach recommended that pure liquor plumbi should be

applied on lint. After a few days the swelling becomes whiter, flatter, and firmer. A mixture of 1 part of tartarised antimony to 2 parts of emplastrum resinæ has been used, and must be continued until pustulation takes place. Again, corrosive sublimate, 4 parts to 30 parts of collodion, causes rapid desiccation, and the application of liq. arsenicalis, or the tincture of iodine, or the compound iodine ointment, has been followed by good results.

Blisters and croton-oil are occasionally used. The application of nitrate of potash causes a vesicle; the moistened finger is dipped in the powder, and the nævus gently rubbed with it.

Vaccination was at one time a favourite remedy; but even if the nævus be cured, it is uncertain whether the patient is protected against an attack of small-pox. If employed it should be done efficiently. Nélaton's plan was to take the finest insect needles, and charge the points with virus direct from the child's arm. Having passed a needle in, it was left *in situ* for a few instants until the tissues had time to become impregnated with the virus. Some surgeons make a point of applying the vaccine lymph at the circumference of the growth. It has been further suggested to inoculate the nævus with pus. The process of tattooing has been employed, using white lead or oxide of zinc, or calcined magnesia, with a sufficient quantity of vermilion or other colouring substance.

The potassa caustica also has its advocates; or the potassa cum calce (Vienna paste) may be used. The paste is spread on the part, and is allowed to remain for ten or fifteen minutes, whilst the skin around is protected by adhesive plaster. Strong nitric acid is a very efficacious remedy, and answers exceedingly well if carefully applied to the strictly superficial variety of nævi; but it often fails in the mixed variety, because the supply of blood, coming as it does from below, is not arrested, and hence the vascular mark may shortly reappear. Again, the actual cautery is very serviceable, and it is recommended by some surgeons to thrust the heated metal in all regions of the vascular mass, central, deep, and superficial. A less heroic form of applying heat is found in placing sufficiently long needles under the growth, and heating the proximal ends with a spirit lamp. Free incisions have also been made in the tumour, and lint or sponge firmly inserted.

The treatment of nævi by the application of ethylate of sodium, introduced by B. W. Richardson, is one that deserves

consideration on the part of the surgeon, its great advantage being that it leaves very little scar, the skin becoming slightly wrinkled, and having the appearance of tissue-paper. The ethylate should be applied, not with a glass rod, but with a brush; the only trifling objection to the latter is that with one use it is destroyed. A quill pen may be advantageously employed.

3. *Injections*.—The next method of treatment is that of injecting some material, of a more or less stimulating character, into the substance of the growth. Numberless chemical agents have been employed with variable success; thus, tannic acid, a saturated solution of alum, carbolic acid and olive oil, dilute nitric acid, pure alcohol, or a strong solution of nitrate of silver are used. The injection of the tincture of the perchloride of iron has been extensively tried with varying results, but all observers now agree that there is some risk in its use, because of the intimate communication that exists between the reticular structure of the nævus and the veins, which are often large; and it is scarcely possible to be quite sure that the fluid is not injected straight into a large vessel. The risk may be reduced to a minimum by adopting the suggestion of first breaking up the tumour, either by vigorous compression with the finger and thumb, or with a couching needle, which is introduced and worked in a radiating or fanlike manner from a single orifice in the skin. The liq. ferri persulphatis has also been used as a good styptic injection. The tincture of iodine is also serviceable, inasmuch as it is not so active an agent as the preparation of iron, for it does not produce coagulation. The injection of liquor ammoniæ appears to be on the same dangerous footing as that of the liq. ferri perchloridi.

4. *Electrolysis*.—Another method which has of recent years attracted well-deserved attention is electrolysis. This method is most simple and efficacious, and while it may be employed with advantage in the superficial or cutaneous nævi, it holds the first place and is *par excellence* the best mode of dealing with the subcutaneous or mixed varieties. Its principle is to coagulate the blood. A Stöhrer's continuous battery may be employed, and about six or eight cells used if the battery is in good working order. One or two needles, which ought to be protected with some non-conducting material so as to preserve the skin, are attached to the negative pole, which is

best made of steel; and one to the positive, which is said to be better if made of gold or platinum, although a charcoal point is preferred by some. These are passed into the tumour. After the needles have been in for three or four minutes decomposition takes place—this is shown by bubbles of gas passing by the sides of the needles. The needles may be withdrawn and re-introduced, and if this process be carefully performed little or no blood exudes. The object of the operation is to produce a clot. It is well not to exceed six or eight cells at first, inasmuch as some children seem to suffer from shock during the operation. Further, if too many cells, say eighteen or twenty, are used, there is a prospect of suppuration. Between six and twelve cells, the writer believes, are the limits; but, as already observed, much depends on the quality and efficiency of the battery. See ELECTROLYSIS.

5. *Setons*.—Setons may be used advantageously in superficial or slightly mixed nævi, but it is important that the threads should be passed well below, and not through, the nævoid structure, their object being to obliterate the vessels passing to the skin-surface.

6. *Ligature*.—The elastic ligature is a favourite method with some surgeons, and is certainly suitable in many cases, but it is uncertain in its action. In treating cases with the ordinary ligature of hemp or silk, it is important to leave as little scar as possible; hence, if the ligature can be applied subcutaneously all the better, and it is worth a primary trial, even if there be a red superficial patch on the skin—i.e. a mixed nævus—because, as the blood-supply comes chiefly from below, there is a great probability that the ligature will not only destroy the subcutaneous growth, but will also eradicate the superficial red spot. Yet it cannot but be admitted that the subcutaneous ligature is often followed by failure, for it is by no means easy to comprise within its grasp one or more important vessels that principally feed the tumour; hence a second or even a third operation may become necessary. Nevertheless, if the operation be successful, the scar left after it is trivial, compared with the results that follow those operations in which the skin itself is included.

Subcutaneous Methods.—A needle in a handle is armed with a long piece of strong hempen thread, and is made to puncture the skin about a quarter of an inch from the circumference of the

nævus. It is then made to pass straight across under the tumour, and to emerge at a corresponding spot on the opposite side. The loop is now held in the left hand, and the needle is withdrawn, still armed with one thread. The needle is re-introduced at the first point of puncture, and is made to go (of course subcutaneously) round the circumference at the right side of the tumour, and to emerge at the same hole on the opposite side. The needle is then unthreaded and withdrawn. Thus there are a loop and one end emerging at one point, and a single thread emerging at the other. This single thread is now placed in the needle, which is again introduced at the first point of puncture, and carried round the circumference on the left side, being made to emerge as before at the opposite puncture. The thread is now removed and the needle withdrawn unarmed. There are now, of course, two apertures—one of entrance, which remains as a pinhole, and one of exit, at which are found the loop and two ends of the continuous thread. The operation is completed by passing the two free ends through the loop, drawing them tightly and tying them, not in a knot, but in a bow, so as to allow of them being tightened, if necessary, from day to day. By this ligature the tumour is cut into halves, and disappears by adhesive or suppurative inflammation.

Ligature involving Skin.—The well-known knot devised by Fergusson is one by which a radical cure may be readily effected. The only drawback to it is that by its use the skin is destroyed; but it is especially applicable to nævi situated on the trunk or other parts not usually exposed to view. Fergusson originally used a needle in a handle, but of late years preferred an ordinary surgical needle. Supposing the latter to be employed, the operation is thus performed:—The needle, having an eye of sufficient size to carry two thicknesses of thread easily, and threaded with a long and strong hempen ligature, is made to enter the skin about a quarter of an inch beyond the circumference of the nævus, under which it is passed. One thread of the loop, it matters not which, is now divided, and its opposite end threaded in the eye still armed. The needle, having now two threads, is made to pass at right angles under the tumour, and on emerging the threads are released. The corresponding ends having been selected, a groove is made with scissors at the circumference so as to receive the threads, and they are tied in a reef-knot as tightly as possible.

This method encircles the tumour and cuts it into four portions. It is important to tie the knots as tightly as possible, so as to ensure the rapid and complete destruction of the disease, and to give the patient as little pain as possible in the separation of the slough.

A modification of the above operation may be advantageously employed. It consists in passing two hare-lip pins under the nævus at right angles to one another, and encircling them with a ligature tied tightly in a bow; the needles are removed immediately after the application of the ligature, and the ligature taken away in twenty-four hours.

7. Enucleation.—This is a very old method of dealing with subcutaneous nævi, but John Bell's dictum of 'cutting out' the tumour and not cutting 'into it' has led surgeons to be over-apprehensive as to hæmorrhage. The idea of alarming hæmorrhage is greatly exaggerated. Some surgeons cut right through the diseased structure and take away each half piece-meal with curved scissors, removing no skin; or turn back rectangular flaps of skin, which should be retained even when involved in the nævoid growth.

8. Écraseur.—This instrument has been used, but can only be recommended in the case of very delicate children.

9. Ligature of Vessels.—1. The principal vessels supplying the nævus have been tied; thus in a case of nævus of the cheek, three needles were placed under the facial, left coronary, and angular vessels respectively, and a twisted suture employed. 2. The ligature of the main vessels has been attended with very negative results. Thus, the common carotid has been ligatured for tumours of the orbit and other tumours of the scalp; but, if this plan of treatment be adopted, it is obvious that the vessel selected should be one that directly supplies the growth, as, for example, the external carotid when any of its branches are involved.

10. Amputation.—This extreme measure can only be necessary in most exceptional cases, and should only be undertaken as a *dernier ressort*.

Summary of Treatment.—As the result of experience, it may be stated generally that for the superficial nævi, either strong nitric acid, the actual cautery, or the ethylate of sodium may be employed; and for the subcutaneous and mixed varieties, electrolysis, the ligature in some form, or enucleation may be practised.

FRANCIS MASON.

NAILS, Diseases of the.—The surgical affections of the nails will be described in the following order:—(1) Hypertrophy and deformity; (2) Onychia; (3) Ingrowing nail; (4) Eczema and Psoriasis; (5) Parasitic disease.

HYPERTROPHY.—Hypertrophy of the nail is not uncommon, and may depend on various causes which induce long-standing congestion of the matrix, or may be merely an accompaniment of old age. Very commonly the hypertrophy is attended by a deformed condition, the nail being irregularly developed and misshapen, becoming extremely thick, and assuming the character of a horn, variously twisted in different cases. Such nails, except from their size, may give no trouble; but, on the other hand, the edge may be directed against the skin, and then the pressure of the boot will cause a sore.

Treatment.—The projecting part of the nail may be removed by means of strong scissors—a groove having been first made with a sharp-edged file; or the nail may be completely removed. In some cases, after the last-named treatment, the nail may be reproduced in a normal fashion; but frequently it is impossible to cure the tendency to reproduction of the deformity, except by paring away the matrix or destroying it, as by strong nitric acid.

The nails sometimes become hypertrophied and misshapen as a result of local nerve-lesions, being remarkably curved and thickened, and in some instances ridged like an oyster-shell; this diseased condition being accompanied by withered and glossy skin and other results of injury to the nerves. The *treatment* is of course that of the nerve-lesion on which the deformity depends. See NERVES, Injuries of.

ONYCHIA.—This term is commonly applied to any long-continued inflammation of the matrix of the nail, which is accompanied by ulceration and its necessary results—purulent and more or less fetid discharge, with loosening and discoloration of the nail. As in many other affections of the nails, the appearances presented by the disease may be alike, although the causes are different. Thus simple, syphilitic, and strumous onychia have been all described.

In a typical and severe case (*onychia maligna*), the extremity of the affected finger is inflamed and bulbous, dark red or livid; foul sanious matter escapes from beneath the nail, which is partly raised from its bed by granulations springing from the ulcerated matrix. All the parts are acutely tender, the patient shrinking from the

slightest touch. Cases such as this are seen most frequently in children, and more often in the fingers than the toes. The disease will be found usually to have begun as a consequence of some injury, as from a squeeze of the finger in a door or from its being trodden upon. In rare cases, the disease may advance until necrosis of the last phalanx occurs.

It is not necessary to assume the presence of a constitutional defect in all cases of onychia; but the possibility of a predisposing cause in the form of struma or syphilis should be borne in mind, and especially when more than one digit is affected. In a case of syphilitic onychia, the symptoms are generally far less acute than when the disease has been caused by injury; and the diagnosis is made sufficiently easy by the presence of other signs of syphilis in the neighbourhood or elsewhere.

Treatment.—The finger should be well fomented with a weak lotion of permanganate of potash or carbolic acid, and a piece of lint dipped in an arsenical lotion (liq. arsenicalis f3j., aq. ad f3j.) should then be applied, the process being repeated twice or three times daily; or, instead of the arsenical lotion, powdered nitrate of lead or iodoform may be dusted over the part. If the disease does not yield to this treatment, the nail should be removed, and the same treatment continued. In syphilitic onychia, black wash or calomel is the best local application; and a course of mercury or iodide of potassium should be given internally. In strumous or cachectic subjects, good food, cod-liver oil, steel, and arsenic are indicated; the local treatment resembling that proper for the simple form of the disease.

In the majority of cases, onychia can be cured by the above-mentioned treatment without much difficulty. In a small number of cases, however, there is some inherent vice in the matrix which leads to a redevelopment of the disease, notwithstanding all treatment; and the only effectual method of cure consists in removal of the matrix, by shaving it off with the knife or destroying it by caustics, of which nitric acid is the best.

INGROWING NAIL.—This term is applied to a very painful affection, in which the irritation caused by the edge of the nail pressing against the soft tissues ends in ulceration with exuberant granulations. The sharp edge of the nail impinges against the ulcerated surface of the skin which overhangs it, not by growing into it, but by the granulations growing out against the edge of the nail. The disease is practically con-

fined to the great toe, and almost invariably to its outer side. When the disease exists elsewhere, it is complicated by some diseased condition of the matrix. Predisposed to by an unusual development of the skin which naturally overhangs the nail, the trouble begins as a consequence of some slight injury, as from the pressure of tight boots or the like.

Treatment.—In a simple case, the edge of the nail should be cut away when any soreness is felt; but when the disease is fully established, and the edge of the nail overlapped by granulations, a more formal operation must be undertaken. Nitrous-oxide gas having been given, or the toe frozen, a slip of the entire length of the nail must be removed by pushing one blade of a pair of scissors beneath it, and twisting off this portion from the matrix with a pair of torsion-forceps. The slip removed should not be more than a fourth, or at most a third, of the nail; and, even if both sides are operated on, a useful central portion will be left. A radical cure can be produced by carrying the scissors well into the matrix of the nail and removing the lateral portion. When there is much overlapping of the skin, a small flap may be sliced off with a scalpel. *See* INGROWING TOENAIL.

ECZEMA AND PSORIASIS OF NAILS.—Any long-continued, however slight, disease of the matrix will produce alteration in the texture and appearance of the nail; and as the altered nail is but a deformity resulting from a disease not primarily in itself, but in the underlying parts, it is only possible to get an accurate idea of the primary disease by studying the condition of the surrounding integuments. Thus, a rugged, furrowed, and brittle condition may be due in one case to eczema, in another to psoriasis, and in another to favus or ringworm, the appearances in all being not very different. Hence the impossibility of describing, in any useful way, the appearances of so-called eczema or psoriasis of the nails. They must be diagnosed in connection with the disease of the vascular tissues in their neighbourhood.

Similar appearances of the nails are sometimes present (and often called eczema or psoriasis) when there is no obvious eczema or psoriasis elsewhere. In such cases, most careful examination should be made with reference to the possibility of local irritation by extraneous matters accidentally applied, the nature of the patient's employment sometimes giving a clue to the source of the disease; or the disease may be parasitic.

Treatment.—When eczema or psoriasis of the nail is accompanied by a like disease elsewhere, the general treatment is obvious. The nails should be kept short, and occasionally softened by applying lint soaked in some alkaline wash, as of bicarbonate of soda (3ss. to f3j. of water). Accumulations of scales, &c., should be removed carefully by a nail-cleaner (made of bone or ivory, not steel). Lotions such as the following should then be tried:—*Liq. carbonis deterg.* f3ss.-f3j., *glycerini* f3j., *aquam ad* f3iv.

The disease is generally obstinate.

PARASITIC DISEASE.—The appearance of a nail affected by parasitic disease is sufficiently like that produced by long-standing irritation from other causes (eczema, psoriasis, &c.) to lead easily to an error in diagnosis. The possibility of the presence of a parasite should, therefore, be always borne in mind. A clue will usually be obtained from the presence of the disease (favus or ringworm) elsewhere: tinea of the nails, for example, in a child being accompanied usually by ringworm of the scalp. But in all doubtful cases a careful microscopic examination should be made of scrapings from the diseased nail; after softening and getting rid of extraneous fatty matters, by the application to the specimen first of ether for a few minutes, and subsequently, for some hours, of liquor potassæ.

Treatment.—The treatment of parasitic disease of the nails resembles that of the same disease when in the scalp or elsewhere. But the uncertainty is greater on account of the difficulty in thoroughly applying anti-parasitic remedies to the diseased surface. Great care should therefore be taken in scraping away the diseased portion of the nail, after softening by means of warm water and alkaline lotions, and in applying the remedies as thoroughly as possible. *See* TINEA TONSURANS; FAVUS.

W. MORRANT BAKER.

NASAL BONES, Fractures of the.
See FACE, Fractures of Bones of the.

NASAL DOUCHE.—To wash out the nose effectually and comfortably, certain simple precautions are to be observed. This process may be required for hæmorrhage, whether accidental, operative, or spontaneous, and is of important use in catarrhal and ulcerative inflammation, especially in the chronic fetid form known as ozæna.

A stream of water or lotion may be passed in at one nostril and out at the other, without impeding the respiration of

the patient if the latter assume the proper attitude, sitting or standing with the chin over the edge of a basin, bucket, or sink, the neck flexed, and the mouth open for breathing purposes. Another vessel contains the water or lotion, which should be an antiseptic liquid, not strong enough to cause pain, but strong enough to disinfect. Nothing is better than a solution of chloride of zinc, averaging an eighth of a grain to the ounce in strength. For hæmorrhage the hottest water that can be borne is far better than cold or iced. In any case plain water does very well to begin with, especially if there be pus, mucus, and scabs to be cleared away. The feeling of the patient may be consulted as to the temperature of the liquid, when used for allaying decomposition and inflammation. Hot or warm liquids, when not demanded for hæmostatic purposes, are better avoided when disliked; for some persons thus experience pain, who can bear and even enjoy cold or iced liquid in a state of nasal catarrh.

The liquid may be washed through the nostrils, in the attitude of the patient as above described, by means of a Higginson's syringe, a convenient method for the surgeon. But when undertaken by the patient, the syphon-tube is invaluable and may be required several times daily. A yard or a yard and a half of india-rubber tubing, transmitting a stream an eighth to a quarter of an inch wide, is slung over the edge of a jug containing the liquid, placed on a shelf or hung against the wall above the patient's head. One end of the tube is weighted, and reaches from the bottom of the liquid to the edge of the vessel, round which it may be curved by inserting six or eight inches of wire to prevent acute flexion and obstruction. The other end reaches from the edge of the vessel to the nose of the patient, and should be considerably longer than the immersed end, to permit syphon-flow when once the tube is filled throughout, and this is readily effected by the patient closing the mouth and opposite nostril temporarily, and taking a deep inspiration through the tube. The tip of the longer end should have a suitable nozzle, ending in an india-rubber 'teat' with a large central hole of a size suited to the nostril.

Nasal douche tubes are specially constructed with neat vulcanite or metal fittings. These consist of a piece of bent stiff tube to hang over the edge of the vessel, or, in the case of a mere stiffening of wire inside the tube at the flexure, a weighted inverted funnel to ensure deep immersion

of the short end of the tube. In either case a nozzle is fitted to the long end. The force of the continuous stream thus produced can be modified by varying the height of the vessel.

RUSHTON PARKER.

NASAL POLYPUS is a growth from the lining of the cavity, more or less pendulous, encroaching upon the breathing space, and on that account accompanied by arrest or modification of nasal respiration. The vast majority are gelatinous-looking objects which can be seen on inspection through the nostril, their presence being first indicated by their obstructive effect. Their point of attachment can never be seen when they are inspected *in situ*, but it is found to be usually on the upper and middle turbinate bones, and, less frequently, the inferior turbinate. Their surface is the mucous membrane of the nose, of which the ciliated epithelium shows abundant vibratile motion when examined microscopically, in a liquid, shortly after removal. Their gelatinous-looking substance is the loosest form of connective tissue, holding mucus in its meshes, and often resembling that class of tumours known as myxoma. They are, probably, mere hypertrophic excrescences of the submucous connective tissue, growing under the stimulus of some constant irritation, and owing their pendulous character to their composition and attachment.

Polypi are common at most periods of life, except in childhood and old age, and may exist in one or both nostrils, singly or in a group. Their lower extremity occasionally becomes excoriated, inflamed, and indurated or distended with blood, presenting, on inspection, under these circumstances, a momentary resemblance to some malignant growths. By pressure upon adjacent parts of the nose they may be attended by a mucous or purulent catarrh, with, in rare instances, ulceration, and even perforation, of the septum.

The *treatment* of polypus is removal, effected by constriction with a wire-loop snare, or by the use of suitable forceps. Satisfactory removal can be practised by either method, and, in some cases, with very little pain or inconvenience to the patient, followed by great subsequent comfort, which is now and then permanent after a single operation.

In using the snare, the wire is passed into the nostril along the floor of the nose, the loop being adjusted as long and as wide as the parts will allow, and then is passed upwards so as to surround the pedicle. This is divided, on constricting the loop, by

means of the *écraseur*, of which it is commonly a part, or, in default of this, by means of a simple piece of metal tubing, such as a piece of broken catheter, which can be slid along for the purpose.

In removing polypi otherwise, a pair of dressing-forceps is more frequently employed than anything else. Such an instrument, finely shaped and fairly long in the jaws, which should be serrated in their whole length, is more convenient than the short, thick sizes. It is not, however, sufficient to deal with polypi from the front, but the left forefinger should be passed behind the soft palate and made to meet the forceps, so as to insure clearing the posterior nares and pharynx, into which large pendulous nasal polypi often hang.

However removed, these 'gelatinous' or 'mucous' polypi, as they are called, have a tendency to be reproduced, at longer or shorter intervals, and accordingly various substances are applied with the view of preventing their re-formation. Tannic acid and sulphate of zinc have been recommended as snuffs. Salicylic acid, also as a snuff, has been used with advantage by the writer; and lotions of perchloride of iron, boracic acid and alcohol, carbolic acid and glycerine, have been known to act satisfactorily in arresting the growth of polypi. The same methods of local medication have been employed in the first instance, the persistent use of tannin snuff having been followed by sloughing and separation of the polypi; and injection of the above lotions into the substance of the growths, by means of a subcutaneous syringe, has resulted in their shrinkage and disappearance.

Other *non-malignant growths* of firmer consistence, and commonly called 'fibrous' polypi, are sometimes met with. They do not arise from the turbinate bones or outer wall, but from some part of the roof, from the margin of the posterior nares, or adjacent pharynx, in which case they are 'naso-pharyngeal' polypi. They are much less frequent than the mucous, much less easy to remove, but still capable of effectual extirpation, although they are commonly attached to the bone beneath them.

Treatment.—Extirpation alone is here practicable. If the growth be pendulous, or have a narrow attachment, the wire snare, plain or galvano-caustic, may be satisfactorily used for the purpose. Certain examples may be removed easily with ordinary dressing-forceps, or the special form alluded to. But, in the event of inaccessibility by what may be called the blind

method of removal, inspection and direct excision should be practised. Some have slit the nostril up towards the eye, others have excised the upper jaw, or temporarily turned aside that bone, subsequently replacing it with its attached soft parts. By all these methods the nasal cavity can be exposed and explored.

But a far better method of entrance into, and inspection of, the nose for foreign bodies as well as tumours within it, is through the mouth under the upper lip, the fold of which is divided along with the nasal cartilages at their attachment to the bone. The nose is raised up with the lip, and a good view can be obtained throughout the nasal cavity, from which the tumour can be removed to its finest detail, without external mutilation of any kind. The writer's personal experience of this method has convinced him of its excellence.

Malignant tumours of the nose, whether polypoid or not in form, are of much less interest than others, being, fortunately, much less frequent, though hardly amenable to treatment at all, and being generally liable to rapid recurrence and eventual fatality. They can be recognised pretty easily by their rapidity of growth, by their tendency to bleed, and sometimes to infect the lymph-glands of the neck behind the angle of the jaw. When purely nasal, their removal may be practicable, and sometimes advisable, by the method beneath the upper lip, as above described, especially if situated far back. If situated in the upper and anterior parts of the nose, it may be easier to operate by direct entrance from the face. See *ROUGE'S OPERATION*.

Such tumours, though arising in the nose, are not infrequently attached to the superior maxillary bone, invading the antrum, or other parts beyond the nasal cavity. In that event, excision of the upper jaw is required, by the methods detailed in the article on the subject (*see JAWS, Operations on the*).

The obviously malignant growths are generally carcinomata, arising from the nasal mucous membrane, exhibiting in their minute anatomy the general characters variously found in carcinomata, with the special features derived from the surface from which they grow. Others have an adenomatous structure and a doubtful malignancy, neither of which can be decided until after operation, the former by microscopical examination, the latter by clinical observation, and waiting for recurrence or its fortunate absence.

RUSHTON PARKER.

NASO-PHARYNGEAL CATARRH.

See RETRONASAL CATARRH.

NASO-PHARYNGEAL GROWTHS.

1. NASO-PHARYNGEAL VEGETATIONS are small pendulous or sessile growths, produced by hypertrophy of the adenoid tissue so abundant in the vault and sides of the naso-pharynx.

Cause.—Hardly known. They are most frequently met with in cold and damp climates, and then generally in delicate children. Colds, the acute exanthemata, and local irritation from food and cold air in cases of cleft palate, have been ascribed as causes. Some regard them as congenital, some as hereditary, and some, but apparently without sufficient evidence, as of strumous or syphilitic origin.

Pathology.—The vegetations occur in greatest abundance in the region of the pharyngeal tonsil, but may also be found on the lateral walls of the pharynx and about the orifice of the Eustachian tubes. They may be soft and friable, or hard and tough, and are generally very vascular. Microscopically, they consist principally of retiform adenoid tissue containing large numbers of lymph corpuscles, with here and there closed follicles similar to those of the tonsil.

Symptoms.—These vary according to the age of the patient, the amount of obstruction to nasal respiration, the vascularity of the vegetations, the copiousness of the secretion, and the condition of the mucous membrane lining the Eustachian tube, middle ear, lower pharynx, and nasal cavities. In a well-marked case, the voice has what Meyer calls a 'dead' character. It is muffled, the nasal resonance is lost, and the *m* and *n* sounds are pronounced as *b* and *d*. The face, from the patient breathing with the mouth constantly half-open, assumes a characteristic vacant expression, similar to that familiar to all in the case of enlarged tonsils; pellets of mucus, often tinged with blood, are constantly hawked up; and blood is occasionally found in the mouth or on the pillow in the morning. More or less deafness is frequently present, and it is often for this that medical advice is first sought. In infants, obstructed and noisy respiration and snoring during sleep should call attention to the affection. Granular pharyngitis, enlargement of the tonsils, and hypertrophic nasal catarrh are not uncommon concomitants; and purulent otitis with permanent impairment of hearing may result if the affection is neglected. A peculiar malformation of the chest,

similar to that which may be met with as a consequence of enlarged tonsils, has not infrequently been observed.

Diagnosis.—The growths can be readily detected by the finger passed behind the palate, and when abundant do not feel unlike, as Meyer expresses it, a bunch of earth-worms. The examination is generally attended with bleeding. In the rhinoscopic mirror they appear as fimbriated fringes, or flattened elevations of a pale, pink, or dark red colour, often encroaching more or less over the posterior nares and orifices of the Eustachian tubes.

Treatment.—The vegetations may undergo atrophy as the patient gets older, or cease to cause obstruction as the naso-pharynx increases in size. But, as the deafness and other symptoms to which they give rise may in the meantime become permanent, they had better be removed as soon as detected. When soft and small, and not very numerous, they may sometimes be got rid of by means of astringent injections or by the application of solid nitrate of silver. The former may be applied by Meyer's tube, which is passed through the nose, or by a post-nasal syringe. But injections, to be of any service, must be persevered in for long periods. If nitrate of silver is used it should be applied fused on the end of a long and suitably bent probe, as the use of all caustic-holders is attended with danger. It should be continued as long as bleeding follows its use. Usually more active treatment is called for. Thus, the softer growths may be scraped off by the finger-nail, a method especially useful in the case of very young children, where the parts are small and rhinoscopy difficult. For tougher and firmer growths, some cutting instrument or the galvano-cautery is necessary. Those situated on the vault may safely be removed by most of the methods that have been recommended; but extirpation by Löwenberg's or Woake's forceps, especially when the growths are of any size, is perhaps the best. When the patient is tractable, and a rhinoscopic examination can be obtained, the forceps may be directed by the mirror. Otherwise chloroform had better be given, and the forceps can then be guided either by the mirror, or by the finger passed behind the palate. Growths on the lateral walls and about the Eustachian tubes must be dealt with more carefully, as here there are important structures in relation with the pharyngeal walls, and an injury of the Eustachian tube may lead to inflammation and even suppuration in the middle ear. In such cases, the patient should

always be placed under chloroform, and the growths destroyed either by a small galvano-cautery, accurately directed by the rhinoscopic mirror, or by Zauffal's nasal speculum, or, as some prefer, by Meyer's ring-knife, which is passed through the nose. To obtain space for the mirror, the palate may be drawn forward by the palate-hook, or better, by fine india-rubber tubing passed through the nostrils out at the mouth and fastened across the lip, the latter method allowing the surgeon the use of both hands. Should any unusual hæmorrhage follow the removal of the growths, it may be arrested by astringent injections, tannic acid insufflations, &c. The patient should be instructed to breathe through his nose; and it may be useful to keep the mouth closed during sleep, either by securing the jaw by a four-tailed bandage, or by the use of the 'contra-respirator' advised by Guye.

2. NASO-PHARYNGEAL TUMOURS OR POLYPI. The term naso-pharyngeal polypus is commonly applied to any tumour growing in the upper part of the pharynx. Such tumours have generally a fibrous or a fibromucous structure; but sarcomatous, carcinomatous, and still more rarely enchondromatous growths may occur. The naso-pharynx may, moreover, be invaded through the posterior nares by mucous polypi, or by malignant or other growths originating in the nasal cavities or antrum.

(a) *Fibro-mucous Polypi.*—These consist of a mixture of fibrous and myxomatous tissue, and commonly spring from the mucous membrane about the posterior nares, which has a structure intermediate to the soft pituitary membrane of the nose and the more fibrous covering of the vault of the pharynx. They are usually smooth, of a soft fleshy consistence, reddish in colour, and ovoid in shape; they are generally pedunculated and hang loosely in the pharynx, sometimes projecting below the soft palate, but more rarely they have a broad base, and send processes into the nasal cavities.

Symptoms and Diagnosis.—Fibro-mucous polypi may give rise to symptoms similar to those of the fibrous variety to be next described. Unlike the latter, however, they are not attended with hæmorrhage, and have no tendency to displace and destroy surrounding parts. They feel, moreover, less firm and resisting to the finger introduced behind the palate.

Treatment.—They may generally be twisted off by the finger or forceps passed behind the palate. If their base is too

broad to admit of this, it may be severed by the galvanic écraseur, in the way described in the next section.

(b) *Fibrous Polypi.*—These generally spring from the periosteum covering the basilar process of the occipital or body of the sphenoid bone, and consist of tough fibrous tissue without elastic fibres, and often intermixed with sarcomatous elements. Their vessels have usually very thin walls, and in some instances are so numerous in parts of the growth as to give it a cavernous structure. They are smooth and firm, and covered with a very vascular mucous membrane, which gives them a dark red colour, while their surface is sometimes eroded by ulceration. They may be either pedunculated or sessile, and at first are usually confined to one side of the pharynx; but as they increase in size they form secondary attachments, displacing and destroying the surrounding bones, encroaching upon the nose, mouth, orbit, or speno-maxillary fossa, and sometimes protruding externally through the nostrils or cheek, or upwards into the cranium. They generally occur in young adult life, grow slowly, are very liable to return after removal, but show a tendency to atrophy after the age of twenty-five. They have occasionally sloughed away spontaneously, and have then shown no signs of return, even after many years.

Symptoms and Diagnosis.—At first there may be no symptoms, but later headaches, drowsiness, and obstruction of one or both nostrils supervene, accompanied by a mucous and often fetid discharge, and frequent attacks of epistaxis. Occasionally, the polypus may be seen through the nose or projecting below the palate; otherwise it may be detected by the rhinoscope, or by the finger introduced behind the velum. As it encroaches upon surrounding parts it may give rise to deafness, difficulty in deglutition, and dyspnoea; whilst the eyeballs may be protruded, the facial bones widened out, and the nose flattened, causing the characteristic deformity known as 'frog-face.' The determination of its attachments now becomes very difficult, but may be facilitated by manipulation with a suitably curved probe. The repeated hæmorrhages produce severe anæmia, and the patient, if not relieved, may die of exhaustion.

Treatment.—When small and pedunculated, a fibrous polypus may sometimes be torn off by the forceps introduced behind the palate. When, however, the attachments are at all extensive, this method should not be attempted, as it may be attended with

profuse hæmorrhage, and, when the bones of the cranium have been invaded by the growth, by fatal inflammation of the brain. For these the galvanic *écraseur* should be employed, the wire loop being passed through the nose, and directed round the base of the polypus by the finger in the pharynx. The stump left after the severance of the growth should then be completely destroyed by the post-nasal galvanocautery, passed behind the palate. The patient should be subsequently carefully watched, and the cauterisation repeated should there be any sign of a return of the growth. When the polypus is too large for removal by the natural passages, the soft palate may be split and, if necessary, part of the hard palate cut away, and the growth then removed by the ordinary or by the galvanic *écraseur*, and the base scraped away from the bone or destroyed by the actual or galvanic cautery. When the growth has taken a forward direction, invading the nose, it may be exposed by turning up the ala of the nose, or by Rouge's method; or, if sufficient room cannot be thus gained, by the removal or resection of the superior maxillary bone after the method of Langenbeck. If the patient is weakened by repeated hæmorrhages so as to be unable to bear a serious operation, electrolysis may be tried—a procedure which, though not invariably successful, has been attended with some brilliant results. Under its use the hæmorrhages have been arrested, and the polypus sufficiently reduced in size to allow it to be removed through the natural passages.

(c) *Malignant Polypi*.—These have generally a sarcomatous or, more rarely, a carcinomatous structure. It is not always possible to diagnose them from fibrous polypi before removal. They grow more rapidly, however, and there is often glandular enlargement and severe pain. Where a small piece of the growth can be removed, a microscopical examination will generally clear up any doubt. When seen early, they should be widely extirpated by one of the methods above described. If they have attained any size, they are beyond the aid of surgery.

NAVEL. See UMBILICUS.

NECK, Diagnosis of Swellings and Tumours of the.—The character of many of the enlargements met with in the neck is in some measure indicated by their position. Thus, bronchocele will be found in the situation of the thyroid gland, while aneurisms are more frequent at the root of the neck. The colour and appearance of the

skin will show the approach of inflammatory swellings to the surface, and in some cases the infiltration of cancer will be recognised in the same way. Upon palpation it will be readily ascertained whether the tumour is fluctuating or solid, or whether it presents a combination of these two conditions. In rare instances, the presence of air in the tissues may be detected by the peculiar crackling sensation communicated to the fingers. This may be due to emphysema from rupture of some part of the air-passages. Hernia of the mucous membrane of the trachea has also been recorded, and occasionally the apices of the lungs can be felt above the clavicles, especially when they have become emphysematous from some intra-thoracic disease. The most important fluid swellings are as follows:—

1. *Abscesses*, which are usually known by their painfulness and rapid growth, together with the signs of inflammation which accompany them. As they generally begin in lymphatic glands, their recognition will be assisted by the detection of any local lesions which may have set up lymphatic irritation.

2. *Cysts*.—Cutaneous sebaceous cysts present no difficulty. Hydrocele of the neck, which is a large collection of serous fluid contained in a single or multilocular sac in the anterior or posterior triangle, is known by its slow and painless growth and by the clear straw-coloured fluid which escapes from the canula when it is punctured. Many are congenital, and they may be associated with solid growth of a sarcomatous type. In the submaxillary triangle ranulæ may protrude as well as in the floor of the mouth, and occasionally deep-seated sebaceous cysts are also found in this region. Bursal tumours may form between the hyoid bone and the thyroid cartilage, and upon the ala of the thyroid cartilage. These, as well as the more common cysts of the isthmus and lobes of the thyroid gland, may be known by their moving with the larynx in swallowing. In hydrocele of the neck and thyroid cysts the contents may be of a bloody character, and blood-cysts are sometimes found, which have resulted from the degeneration of nævi. Hydatid cysts and cysts of the *cysticercus cellulosæ* may occur in the neck. They are very rare, and will probably not be recognised until a puncture has given exit to clear watery fluid, containing hooklets or pieces of cell-wall.

3. *Aneurisms* are known by their expansile pulsation, and by their position upon the course of great arteries. At the

root of the neck they may be in connection with the arch of the aorta, the innominate, the subclavian, or carotid arteries. Bruits heard upon auscultation, and differences in the character of the radial pulse of the two sides, will assist the diagnosis. There may also be evidence of pressure upon the recurrent laryngeal nerve. There will be less difficulty in recognising the position and character of the disease when the distal portions of the carotid or subclavian arteries are affected.

The *solid* swellings may be classified as follows:—

1. *Glandular*.—These are usually the result of chronic inflammation, and they are frequently associated with scrofula or syphilis. Some are secondary to malignant affections in their vicinity. Cancer of the lip or tongue is the most frequent cause of these enlargements in the upper part of the neck, while the supra-clavicular glands may be implicated in scirrhus of the breast. Enormous growths of a primary character are found in the various forms of lymphadenoma. Some of these are very malignant, infiltrating the deeper structures as well as the integuments.

2. *Nævi* and other tumours of the skin and subcutaneous tissue are frequent. Papillomata are sometimes observed, which appear to have some connection with the branchial clefts of the developing foetus.

3. *Lipomata*, which may be of the common lobulated and encapsuled form. It is in this region, however, that we generally find the rarer diffused fatty tumour. This may either invade the front of the neck, where it looks like an enormous double chin, or it may form an unsightly prominence covering the nape of the neck. Small masses of fat have been observed in the supra-clavicular regions associated with absence of the thyroid body, in sporadic cretinism.

4. *Bronchoceles*, which will be recognised by their position and by their movement during swallowing.

5. *Growths in Muscles*.—Gummatous swellings due to tertiary or hereditary syphilis may attack any of the muscles, and in infants the sterno-mastoid is especially liable to localised induration, which may sometimes arise from congenital syphilis; but far more often it is produced by severe strain during the process of parturition, such as the traction upon the muscles while the head is being delivered in a footling presentation.

6. *Malignant and semi-malignant tumours*, of which the sarcomatous affection

of the lymphatic glands already mentioned is the most common form. Epithelial cancer sometimes occurs primarily in the skin, or it may spread from some deeper seat in the air and food passages. The implication of adjacent tissue and glands, the age of the patient, and in many cases the rapid growth, will assist the diagnosis of these tumours. N. DAVIES-COLLEY.

NECK, Inflammatory Affections of the.—Cutaneous erysipelas rarely attacks this region except when it spreads from the face. Erysipelatous and phlegmonous inflammations of the fauces are apt to invade the larynx, where they give rise to grave symptoms, from œdema glottidis.

Stiff-neck is a congestive inflammation of the fascial or muscular structures, due to cold draughts, chills after exertion, or strains, especially of the sterno-mastoid muscle. It comes on suddenly, with a good deal of pain, which is aggravated whenever the patient attempts to move his head from the constrained position in which it is held by the spasmodic contraction of the muscles. Usually it disappears spontaneously in a day or two, but more rapid relief can generally be procured by warm applications, or, still better, by the domestic remedy of covering the part with flannel, and then ironing it over with an ordinary flat-iron as hot as can be borne. A gentle aperient, followed by half-drachm doses of citrate of potash, will also be beneficial.

Abscesses of the neck may be diffused or circumscribed. The latter are usually set up by inflammation of the lymphatic glands, which are very abundant in the deep as well as the superficial strata. In the upper part of the neck, abscesses are frequently secondary to ulceration of the mouth, fauces, and pharynx. If farther back, they are often caused by eruptions of the scalp. Alveolar inflammation and necrosis of the lower jaw occasionally give rise to abscesses in the submaxillary region. At the root of the neck, abscesses may receive an impulse from the subjacent arteries, and there may be considerable difficulty in distinguishing these from aneurisms. Diffuse suppuration may originate in the glands, but it is more often the result of a contusion or exposure to draughts. It is usually met with in adults of a somewhat enfeebled constitution. There is rapid swelling, with redness of the skin and brawny hardness, which is soon followed by softening and fluctuation. The tissues involved are generally beneath the deep fascia, and they may be either in the space which intervenes

between this and the fascia investing the depressors of the hyoid bone, or still deeper, beneath both the fasciæ. In the latter case, there is great danger of the inflammation spreading down into the mediastinum and lighting up pleurisy or pneumonia. Sometimes also death has occurred from the perforation of one of the large vessels of the neck.

Abscesses should be opened early, to prevent their spreading beneath the fascia, and also on account of the unsightly scars which they leave behind when allowed to make their way to the surface. It is still more important to give exit to the matter by early incision when the suppuration is diffuse. In many cases this treatment should be adopted even before the brawny swelling has begun to fluctuate, and, after the incision, careful provision should be made for the free discharge of the matter through drainage-tubes.

Occasionally abscesses develop at a still greater depth, beneath the prevertebral fascia. They are usually the result of disease of the bodies of the cervical vertebræ. By bulging forwards they obstruct the pharynx and œsophagus, and thus hinder the passage of food. They also tend to spread sideways and reach the surface in the posterior triangle of the neck; or they may run downwards into the posterior mediastinum, and burst into the pleura or pericardium. As soon as a fluctuating tumour is detected at the back of the pharynx, it should be opened in the middle line by a knife introduced through the isthmus of the fauces; or an attempt may be made to open it aseptically by dissecting down upon it from the posterior triangle of the neck, and introducing a drainage-tube.

N. DAVIES-COLLEY.

NECROSIS.—Necrosis is the term used to denote, in bone, what is expressed by the word sloughing when speaking of the soft tissues. It implies that a portion of bone has died *en masse*, whereas caries signifies molecular death or ulceration. Thus necrosis and caries of a bone have their counterparts in sloughing and ulceration of the soft tissues.

Necrosis may affect only the cortical part of bone, and is then called peripheral. This is probably the most common form. The cancellous tissue alone is rarely involved, except in a localised osteomyelitis, in which case it might be called 'central necrosis,' but the symptoms, pathology, and treatment are the same as in chronic abscess. When the whole thickness of a

bone is necrosed, as sometimes occurs in acute diffuse periostitis, it is called 'total necrosis.'

Causes.—Necrosis is much more common in some bones than others, the long bones being by far the most frequently affected, whilst the short and flat bones are, comparatively speaking, but rarely so diseased. No age appears to be really exempt, but the young undoubtedly suffer most. Between the ages of twelve and eighteen it is most common, attacking the poor and ill-nourished with far greater frequency than the healthy and well-to-do.

Everything which tends to interrupt or impede the circulation and nutrition of a bone, whether it be in the periosteum, medulla, or in the bone itself, may give rise to necrosis. Thus it is a common sequel to the various inflammatory diseases of bone, but it may also occur by extension of inflammation from the surrounding parts, as in whitlow. Of external causes, injuries such as wounds, bruises, compound fractures, amputation, and gunshot injuries, are the most frequent. Extreme degrees of heat and cold, such as frost-bite and burns, may also give rise to necrosis. Of internal causes, the specific fevers are the most definite. During convalescence from scarlet fever, measles, smallpox, typhoid, typhus, and rheumatic fevers, some inflammation in one of the long bones or its periosteum is not infrequently observed. This may end in the death of a small portion of bone.

Syphilis also gives rise to necrosis by ulceration and destruction of the soft parts over a bone, or by inflammation of the periosteum, as is described under chronic PERIOSTITIS, or by condensing OSTITIS, a disease in which the Haversian canals may become so nearly obliterated as to lead to obstruction of the circulation in a portion of the shaft. Mercury and phosphorus have also been known to cause necrosis, but are now more rarely the direct exciting causes than they were in former times. Other constitutional states there may be, which predispose to inflammation of bone and its consequent death; but little more can be said, except that feeble, ill-nourished children of the strumous type are more prone to it than the healthy and robust.

Pathology.—The inflammatory conditions of bone, which may arise from any of the above causes and produce necrosis, have been described under OSTITIS, PERIOSTITIS, and OSTEOMYELITIS, and need not be repeated here. A portion of bone being dead, either as a direct consequence of inflammation, or, as in a compound fracture,

from its exposure and separation from the periosteum and surrounding parts, we have now to consider how the dead is separated from the living bone and removed from the body. The process is accomplished by inflammation and suppuration, if this condition be not already present as the exciting cause of the necrosis. The living bone and periosteum surrounding the dead become inflamed. That part of the inflamed area which is in immediate contact with the dead breaks down into pus, whilst the peripheral or outlying part is forming new bone. The various stages of the process will be found described under rarefying OSTITIS.

As the Haversian canals dilate and inflammatory exudation is poured out into the tissue surrounding the vessels, new capillary loops are formed and become covered with leucocytes. This inflammatory new-formation is converted into granulation-tissue, which, eventually producing fluid pus, forms a line of ulceration separating the dead from the living bone. In the peripheral parts, especially in the periosteum covering the dead bone, the inflammatory new-formation, instead of becoming granulation-tissue, develops into new bone invaginating the old. This new bone forms a more or less complete casing, leaving an aperture here and there for the escape of pus. These openings are called 'cloacæ,' and the dead bone locked up within the new ensheathing bone, when loosened from its surrounding parts, is called a 'sequestrum.'

On the superficial aspect of the tibia, if the periosteum has been destroyed, this invaginating sheath may be absent, and the dead bone is not encased as above described. Exfoliation, which is the term used to express this process of removal without invagination, occurs also not infrequently in the skull. It is, however, only in the superficial or peripheral necroses that such exfoliation can occur. Reproduction of bone after the removal of the sequestrum is generally fairly perfect. The periosteum being the principal agent in the formation of this new bone, we find that in the cases of exfoliation, especially of the tibia and skull in which the periosteum has been completely destroyed, the gap is generally filled up by granulations which organize into a firm fibroid tissue. In the deeper parts of this new cicatricial tissue some bone is reformed, but to a great extent a groove in the bone remains, which is filled as above described. This is especially so in the case of the skull. In cases of total necrosis, where there is a perfect invaginating

sheath, the reproduction of bone is almost perfect, even when the necrosis has involved the whole shaft from epiphysis to epiphysis, provided the epiphysis itself and its cartilage are intact. In cases where the epiphysis is involved and partially or completely destroyed, the reproduction is more or less imperfect.

The *symptoms*, at first, are generally those of one of the antecedent inflammations of bone, and presumably the abscess that has formed has been opened, or has been discharged without the surgeon's assistance, before coming under observation. He has now to consider the best means for detecting the presence of dead bone beneath, its probable size and character, and the possibility of its being loose and fit for removal.

Firstly, with regard to the actual presence of dead bone; the history of an attack having the characters of one of the inflammations of bone would point in this direction. One or more sinuses having button-like, pouting granulations, with considerable enlargement of the bone beneath, would increase the probability; and the introduction of a probe, which strikes with a clear ringing sound upon the hard non-vascular sequestrum, will confirm the opinion already formed.

Secondly, as to its size and character; a small and superficial necrosis will be attended with a small amount of discharge, and very little enlargement of the bone affected; there may be few openings close together, or possibly only one sinus may be present. Moreover, it can be seen and felt quite close to the surface. In the case of a large extent of both surface and thickness, as in total necrosis, there will be a very copious discharge, a large development of new bone, and several sinuses at considerable intervals from one another; and, on examination, the probe will pass through new bone for some distance before it strikes upon the sequestrum.

Lastly, its fitness for removal will depend on whether it has become loose. The length of time that has elapsed, since suppuration was first fully established, will be the first point for consideration. In the very young, necrosed bone is much more quickly separated from the living than in the young adult. The rapidity diminishes with age till the full adult period is reached. In the old, the process of separation is oftentimes very slow, on account probably of the feeble circulation. The superficial necroses are more quickly separated than the central and total necroses. The total

necrosis of acute diffuse periostitis is an exception to this rule; if the whole shaft up to the epiphysial line has died, it will be very quickly loosened from its connections. The periosteum has already been stripped from the bone, and the cartilaginous epiphysial line is easily disconnected from the shaft. The rapidity with which a necrosed portion of bone will separate, depends also on the particular bone affected. Those of the upper extremity are more rapidly loosened than those of the lower, probably on account of their greater vascularity. In the young adult, two to three months will probably be about the average length of time for the bone to become loose in the lower extremities, whilst in the upper, the average would be about six weeks to two months. When thoroughly loose, the probe on striking the dead bone often produces a hollow note. Two probes may also be introduced into two different sinuses, and by alternate pressure a movement of the sequestrum may be effected; or, in case of exfoliation, a director may often be introduced beneath the edge of the sequestrum, which is then tilted up and felt or seen to move.

The *prognosis* must necessarily vary very greatly according to the extent of the necrosis, the bone that is affected, the proximity of the disease to a joint, and the constitution of the patient. We have also to bear in mind that, in old and long standing cases, amyloid disease of the viscera is liable to ensue, as it does in caries.

Treatment.—Free incision for the evacuation of pus is the first and most important consideration. Dependent openings should be made wherever it seems likely that pus would have a tendency to gravitate. Absolute rest should be obtained either by a splint or pillow. Antiseptics should be so far carried out as to prevent decomposition and putrefaction of the discharge, but, in the writer's opinion, it is not necessary to employ the rigid Listerian method throughout the prolonged treatment of such cases as these. When the abscess is first opened, especially in chronic cases (e.g. syphilitic), it may be wise to do so in the hope that necrosis may not ensue. In acute diffuse periostitis it will be found, however, a vain hope. Putrefactive bacteria are already present in the pus before it is evacuated, and necrosis to a greater or lesser extent invariably ensues. The exceptions to this rule are so rare as to be beyond the scope of this article. Such material as the salicylic, iodoform, or wood wool, firmly applied with a bandage and

changed once a day, is generally sufficient. It absorbs the discharge and prevents it from decomposing. This also enables the surgeon to see, at the earliest possible moment, when a still more effective opening may be made for the evacuation of pus.

When the time comes for the removal of sequestra, to which allusion has already been made, ether will have to be administered and possibly a tedious operation undertaken. In most cases Esmarch's bandage will be found of great assistance, enabling the operator to see clearly when he has removed all the dead bone. The cloacæ being enlarged or thrown into one another by the chisel, gouge, or one of the various forms of cutting bone-forceps, the sequestrum is seized by a pair of large necrosis-forceps and extracted. If there is any difficulty, such as may arise from both ends of the sequestrum being still under cover of its ensheathing bone, it may be divided into two parts and then easily removed. Of course, a small sequestrum can often be removed with only a slight enlargement of the sinus, and the application of a small pair of dressing-forceps or a director. In the case of an exfoliation there is still less trouble, as it only requires lifting from its bed.

As regards general treatment, the patient may require considerable care and attention, especially in the case of acute diffuse periostitis, to keep his powers in a fit condition to cope with a prolonged and exhausting disease. Good, wholesome nourishment should be frequently given, wine or brandy being added according to the particular case in hand. The more a patient can take and assimilate, the better chance he seems to have of living through such an illness as that produced by a severe necrosis.

H. H. CLUTTON.

NEEDLES.—The suture-needles in common use are either straight, 'semi-curved'—i.e. curved towards the point—or full-curved, i.e. curved along their entire length. The straight needles are the easiest to introduce, and are the best for stitching together large surfaces, such as amputation-flaps; the curved needles are not so easy to use, but are very serviceable in regions which are depressed below the surrounding parts, such as the angles of the eye, or in cavities, such as the vagina. The 'full-curved' needles should be held between the forefinger and thumb, and introduced by a movement of supination; a needle-holder is a great assistance when very small curved needles are employed. For carrying

silk, catgut, or horsehair, an eye like that of an ordinary sewing-needle answers very well; but it does not do for wire, as the loop of the latter is too bulky, and is liable to slip from its place and check the passage of the needle. To meet this difficulty several special needles have been invented. In one the wire is screwed into a female screw at the end of the needle; in Lister's needle the eye is placed laterally, and is deeply grooved so as to carry the wire. Price's needle has two eyes, placed one in front of the other, and is deeply grooved: to thread it, pass the wire from before backwards through the posterior eye, next in the opposite direction through the anterior one, and, finally, turn the end of it sharply backwards into the groove on the anterior surface of the needle. Murray's needle contains in the blunt end a conical canal, the larger end of which opens in a groove on the side, and the smaller at the heel of the needle; the wire is passed in at the heel of the needle, and projected at the side of it; the tip of the wire is then turned down and pulled back till it is jammed in the conical canal. Ward-Cousins has introduced, or re-introduced, a needle and wire all in one piece.

Tubular needles are also used for passing wire sutures, and Startin had them so made that, whilst capable of being used separately, the two together form part of an ellipse, and when passed from opposite sides of the wound one fits into the other; a complete tube is thus formed, through which the wire may be passed, so that, on removal of the needles, the wire will remain *in situ*. The tubular needle is very useful for passing wire sutures in the operations for cleft-palate and vesico-vaginal fistula. For the former operation T. Smith has invented an instrument, which consists of a tubular needle at the extremity of a long handle, to which a reel is attached to hold the wire, and a wheel to project it through the tubular needle. A very similar instrument was described by P. C. Price in 1860. Spencer Wells has devised a needle with an 'opening eye,' so that a loop of thread may be removed from it without being cut; it is of special value where the quilled suture is used. Spencer Wells has also devised a needle with a notch near the point, for use in operating for vesico-vaginal fistula; the suture is passed through one side of the fistula with a *nævus*-needle, and the notched needle passed through the other side; the loop of the suture is then caught by the notch, and, as the needles are withdrawn, the suture is left in position.

The name, '*nævus* needle,' is applied to a sharp-pointed needle on a handle, which has the eye near the point; and '*aneurism* needle' to one which differs from the last-named in being more curved and blunt-pointed.

HAGEDORN'S NEEDLES are flattened laterally, and are of equal width and thickness from the eye to the point. They have a cutting edge, which resembles a Beer's cataract-knife, on the convex border of the needle near the point. The eye is placed laterally, as in Lister's needle for wire sutures, but it is not grooved. The advantages of these needles will be evident, if the wounds they make be compared with those made by the curved needles in common use. The latter, being flattened transversely to the curve, make an incision parallel with the direction of the wound, so that when the suture is tied the incision made by the needle is pulled into a triangular wound, which does not always heal by first intention. Hagedorn's needle makes an incision at right angles to the direction of the wound, and consequently in the line of traction of the suture, so that the latter will rather tend to approximate its edges, and so interfere as little as possible with primary union of the needle-puncture. The greater strength of the needle which results from its being curved on the edge instead of on the flat, prevents its being bent out of the desired course when it penetrates indurated tissues, and the direction of the wound which it makes involves less damage to nerves and tendons in suturing operations.

Hagedorn's needle for suturing intestines has a rounded point instead of the cutting edge described above.

BILTON POLLARD.

NEPHRALGIA, or pain in the kidney, may be produced by a variety of causes, and it appears likely that the list of these will, as the result of further study, be extended far beyond its present limits.

The most common cause of nephralgia is the presence of calculus in some part of the kidney. We are not yet in possession of sufficient facts to enable us to indicate exactly the situation of the stone, nor are we able from the character of the pain alone to estimate its size. It may be said generally, however, that where the nephralgia is paroxysmal, the stone is more likely to be in the pelvis of the organ and more or less movable, and *vice versa*. The pain is usually dull and aching, and referred to the situation of the kidney; but it may be

sharp and spasmodic, and radiate down the side into the testicles, or to the tip of the penis. It is increased as a rule by pressure over the kidney, and usually also on movement of the body, and is sometimes severe enough to produce nausea, or even vomiting. This is especially likely to take place where a stone is lodged in the commencement of the ureter, and is being forced into the latter, giving rise to bleeding and, probably, plugging by clot. The whole assemblage of symptoms associated with the passage of a stone or clot into the ureter is known as RENAL COLIC.

Nephralgia is also produced by new growths in the kidney, but, probably, not usually until they have either commenced to cause distension of the pelvis, blocking of the ureter by growth or blood-clot, or change of place of the kidney itself with more or less drag on the pedicle. This change of place must always occur where the organ is much enlarged from any cause; the increase of size finds no room above on account of the diaphragm, and can only take place downwards and inwards. Gravity also plays a part here, and it also appears not improbable that the muscular action of the ureter, under irritation, may actually drag somewhat upon the mass. Nephralgia is also produced by tubercular disease of the kidney, and in at least three ways—(a) by ulceration, (b) by the production of blood-clots and consequent block of the ureter, and (c) by impaction of tubercular shreds in the latter. Of course, blood-clot due to injury of the kidney from any cause will also produce renal pain, either continuous or paroxysmal. Again, shrinking of the whole organ after interstitial nephritis may produce a neuralgic condition, and cystic dilatation has been known to produce the same thing. Cases are on record where, on exposure and removal of a kidney on account of severe pain and the suspicion of stone, nothing has been found but a small shrunken organ. Slight pyelitis, too, may cause pain, either as the result of the inflammation alone, or by producing more or less blocking of the ureter by a swollen mucous membrane. Then again, nephralgia often accompanies a movable kidney, and probably is due here to the dragging on the nerves of the pedicle, produced by the change of position of the organ. Finally, there are cases in which patients have suffered severe pain for years in the kidney and yet, after death, nothing has been found in the organ to account for it, the cause remaining as obscure as in the case of many other neuralgias.

The *treatment* of nephralgia will, of course, vary very much in different cases, since it is but a symptom of a variety of different conditions. Where, for reasons given in discussing the various objectively morbid conditions of the kidney, no local treatment of the organ is possible, we shall best deal with the nephralgia by enjoining perfect rest in the recumbent position. Next to this, warm applications to the flank will be most suitable. After these measures have failed, we have little left but the usual anodynes.

A. E. BARKER.

NEPHRECTOMY, or the removal of the whole kidney, is a measure unknown as a formal operation until the last few years. Any detailed history of the operation would be out of place here, and it need only be said that it was first performed on the human subject, as a definitely planned procedure, by G. Simon of Heidelberg on August 2, 1869, he having previously shown by experiments on dogs that it was feasible and physiologically safe. Before Simon's case the kidney had been removed, on a mistaken diagnosis, twice completely in America, and once incompletely in Germany; but the first impetus to the study of the whole question of nephrectomy, as a definite surgical procedure, dates from the publication of Simon's successful case and of his numerous experiments, in 1871. In this country the operation was first done by Dr. Meadows in 1871, under the impression that the tumour dealt with was an ovarian cyst; then by Mr. Durham, rather as an exploratory measure for a painful tumour of the flank. The first British surgeon to perform nephrectomy designedly appears to have been Mr. Jessop of Leeds, whose patient, a child of two and a half years of age, from whom he removed the kidney for encephaloid disease in January, 1877, recovered and lived several months afterwards. Within the last few years, the kidney has been frequently excised for various morbid conditions, in England and elsewhere, and the knowledge of the condition requiring this treatment, and of the details of the operation, has increased rapidly with the publication of every case, unsuccessful as well as successful. But in spite of the long array of nephrectomies now before us, much difficulty remains in deciding as to the choice of cases in which this procedure should be adopted, and the exact method to be followed. Nephrectomy has been performed now for renal neoplasms, for calculus, for pyo- and hydro-nephrosis, tubercular kidney, injury to

and rupture of the organ, and for floating and painful kidney, and the reader is referred, for the consideration of these conditions, to the special heading of each. The question remaining for us now is the method of procedure, and here there is still much difference of opinion, which must last for a considerable time to come. There are, however, some general conclusions which may be considered as fairly established, and these will be alluded to when the various methods have been described.

There are three points in the abdominal walls at which the kidney may be removed—(1) in the loin, at the outer border of the erector spinæ muscle; (2) at the outer border of the rectus abdominis muscle; (3) in the linea alba. The chief advantages of the first of these methods are that the peritoneal cavity is not opened, that no important structure is wounded in reaching the kidney, and that the wound can be freely drained, from behind, without much risk of infecting the peritoneum. The main advantages in opening the abdomen at the outer border of the rectus (Langenbuch's incision) are, first, that the kidney and its pedicle are here most easily reached, and this not through the anterior layer of the meso-colon, which contains large veins, but through the posterior or external layer, which has very few vessels; secondly, the operation wound in the perinephral tissues can be made practically extra-peritoneal, by stitching the outer layer of the meso-colon to the anterior lip of the incision in the abdominal wall early in the operation, and so shutting off the general cavity of the abdomen from that left behind by the removal of kidney, which can now be freely drained. The strongest reasons for choosing the third method of removal—i.e. by median abdominal section—are found in the fact that freer access is thus gained, not only for the removal of larger renal tumours and ligature of their pedicles, but also that the state of the opposite kidney can by this means be ascertained, by passing the hand across the abdomen, and actually feeling the organ with the fingers. It is necessary, however, to mention that though the hand may reach the kidney opposite to the one it is proposed to excise, its soundness or the reverse cannot be ascertained by mere palpation. Great enlargement, or, on the other hand, great reduction, in size or complete absence might be detected; but the organ might be tubercular, or fibroid, or contain a moderate-sized calculus, and yet the hand be unable to detect the condition. This

plea for the median incision cannot, therefore, be allowed to have much weight.

The chief objections raised to the first or lumbar method are, that the organ is more difficult to reach from behind, especially its pedicle; also, that the space between the last rib and the iliac crest is too limited for the removal of large tumours; finally, that the condition of the opposite kidney cannot be ascertained by direct examination. The drawbacks to the second or lateral incision are that the peritoneal cavity is opened, and also that if the tumour cannot be removed without the escape of some of its contents, it is not so easy to drain, without contamination of the peritoneum, as in the first method. Also, that if there be any oozing of blood, it is likely to find its way into the cavity of the abdomen, both during and after the operation. The liability to hernia at the seat of incision appears to be greater here than at the more posterior wound. The same reason may be urged more strongly against the median method, where the difficulty of keeping the peritoneal cavity clean is still greater under all conditions. Besides this the intestines may be much in the way, and give rise to great trouble by protruding from the wound. Further, the anterior layer of the meso-colon must be divided to reach the kidney, and here there is much risk of bleeding, from the large size of the veins running through it.

A careful review of all the arguments, for and against these several procedures, and their results, justifies the conclusion that each has its proper place in surgery, and that it remains for future experience to determine the exact conditions under which each should be adopted. For the present, it may be said generally that, for the larger solid and non-inflammatory tumours (if these are to be operated on at all), abdominal section is to be preferred; while, for the fluid tumours of the kidney and inflammatory conditions, one of the lumbar incisions is best suited.

Something remains now to be said as to the details of each method of performing nephrectomy. First of all, in every case the strictest antiseptic precautions should be observed from beginning to end. The lumbar incision is the same as that in NEPHROTOMY, until the surface of the kidney is reached. The subsequent steps of the operation are determined by the condition of the organ. If its surface be quite unaffected by present or bygone inflammation, it is easily and rapidly separated by the finger from the surrounding

fat until the pedicle is reached. This is true, whether we are dealing with a healthy kidney, or one in which there is a stone, or a new growth, or a collection of cysts the result of obstruction. But, if the organ have become adherent by inflammation to the perinephral fat, itself condensed and shrunken so that it forms one firm tough investment intimately united with the capsule, it is best to enucleate the kidney out of the latter, leaving it behind with the condensed fat. Indeed, it is not possible to do otherwise in many cases, for the material surrounding the kidney is so tough that it can hardly be torn with the finger, and so vascular that, if at all roughly dealt with, it bleeds so freely as seriously to endanger the patient's life. This process of enucleation is rarely a difficult one, if the surface of the kidney is closely followed, no matter what the amount of condensation of the tissues around may be; but if this guide is lost, and the finger is carried into the surrounding tissues, the difficulties are enormously enhanced. These general rules will be found serviceable for this part of the operation, but beyond them each case must be treated on its own merits.

Having reached the pedicle, the vessels are ligatured in two bundles with stout carbolised silk, passed through the middle of the mass and tied over each half in succession, and then round both together. The ureter may be either simply divided or tied with the vessels, or by itself later, and may either be left in the wound or, perhaps better, be drawn to the surface and secured there in the angle of the skin incision, so that no regurgitation may take place into the wound. This might be a serious matter if the ureter were dilated and full of foul urine or pus, which, escaping into the wound, would render it septic.

After this, the organ may be removed by a few snips of a scissors as near the kidney as possible, or even leaving a little of its tissue if sound. This tissue will soon cease to secrete and become fibrous, when the renal vessels are once tied. The ligatures, in some cases, have to be applied while the kidney is *in situ*; in others, the organ can be lifted out of the wound beforehand. But, in whatever way the act is performed, every care should be taken to avoid dragging upon the pedicle, whether in passing the aneurism needle through it, or later in manipulating the organ, every such strain adding materially to the shock of the operation. The writer has endeavoured to ascertain the effect upon the circulation of ligation of the pedicle in several cases in which

he has performed nephrectomy, by having the pulse carefully watched throughout, and in the last case by having a sphygmographic tracing of the pulse made while the operation was proceeding. He has found that the pulse is not very much affected to the touch, but the tracing showed some irregularity during the process of manipulation of the organ, followed by increased arterial tension when the pedicle was ligatured. These observations, however, will require to be repeated frequently before we shall be able to pronounce positively upon this point. The ligatures should be cut short in aseptic cases, but, where there is suppuration, it is better to leave them long and carry them out of the parietal incision, and wait for their coming away in the usual manner. This they will not do in a perfectly aseptic wound, but become encapsuled, giving no further trouble. As to the relative merits of catgut and silk, this is not the place to discuss them. It may be remarked, however, that most surgeons prefer silk for this part of the operation.

After division of the pedicle, it only remains to insert a drainage-tube (which should be large and long), and to close the external wound with a few wire or silk sutures, all blood-clots having first been removed from the perinephral space. An antiseptic dressing is then applied over all. It is well in these operations to remember the occasional presence of aberrant renal arteries, entering as they may any point of the concave surface of the kidney. They may be met with at any stage of the operation, and, if great care is not observed, may be torn across, and should always be looked for and secured as early as possible.

Nephrectomy by lateral abdominal section (Langenbuch's) is thus performed:—The patient lying upon the back, an incision about four inches long is made at the outer border of the rectus muscle through the tendinous tissue of the linea semilunaris. Any slight bleeding having been stopped, the peritoneum is opened, some part of the colon presenting most probably in the wound. This is gently pushed inwards, on which the external or posterior layer of the meso-colon is exposed. In this there are no vessels of importance, and the incision through the peritoneal layer may be made in almost any direction suitable for the removal of the kidney, but a vertical line is to be preferred. If the tumour to be removed contain fluid, whether urine, pus, or blood, it may now be wise to unite the anterior lips of both peritoneal wounds—that of the abdominal wall and that of the meso-colon

—closely together by catgut sutures, so as to shut off the general cavity of the abdomen from the perinephral space about to be freely intruded upon. By this measure, if the fluid in the tumour should burst its covering, it is prevented from contaminating the whole abdomen, and can flow freely out of the parietal wound. If this is done, moreover, a drainage-tube may be inserted through the front abdominal wound into the post-peritoneal space, after removal of the kidney. In other respects the rest of the operation is performed exactly as that in the median line described below. Access to the kidney and pedicle is much easier in this lateral operation than in either of the others; but an examination of the opposite kidney is not so easy as with a median incision.

In nephrectomy by median abdominal section, the steps of the operation up to the actual enucleation of the organ are almost the same, generally, as in OVARIOTOMY. The division of the abdominal muscles and peritoneum, and the precautions to be observed throughout as to bleeding, treatment of the intestines, &c., are alike in both procedures. But when the bowels have been drawn aside and the anterior layer of the meso-colon has been reached, the special difficulties of the nephrectomy commence. First of all, a transverse incision is made in the anterior layer of the meso-colon, great care being taken to avoid wounding the large veins, which run usually transversely across the diseased organ. If necessary, these should be secured by double ligatures and divided, which is better than running any risk of their being torn in enlarging the opening or getting out the kidney. Then, the organ is separated from its surroundings by the finger swept either outside or inside the capsule, according to the amount of destruction of fat by inflammatory sclerosis, or the absence of this process (*see above*). Sometimes this process of enucleation is very easy, and accompanied by but little bleeding, as in the case of renal new-growths of moderate size; sometimes it is extremely difficult, especially where inflammation has existed for a long time in the kidney. When the pedicle has been reached, the organ can be lifted out of the abdominal wound and the vessels and ureter secured, as in the lumbar operation (*see above*). Then the organ is removed with the scissors, and the pedicle is allowed to slip back into the post-peritoneal space left by the enucleation. Nothing now remains to be done but to clean out all blood-clots from this space, close the peri-

toneal wound over it with catgut stitches, carefully cleanse the peritoneal cavity, and unite the edges of the abdominal wound with silk, as in ovariectomy, a gauze or salicylic-wool dressing completing the operation. If there be any indication of likelihood of effusion of blood or serum into the post-peritoneal space, a knife-blade may be thrust through the lumbar abdominal wall, from within, at the point of election (*see NEPHROTOMY*), and a drainage-tube inserted to drain this space, which is then shut off from the general cavity of the abdomen by suture of the edges of the peritoneal wound with catgut.

Any comparison of the results of these three methods of performing nephrectomy, and their relative mortality, has at present but little value as a guide in the choice of an operation. The diseases for which they have been employed are so various, and the stages of these affections at which nephrectomy has been performed so very different, that no reliable conclusions can be drawn from mere statistics. The author's attention to the whole subject has been very close for several years, and his personal experience of the operations considerable, yet, at the present moment he is unable to profess any decided leaning to one method more than another, speaking of the removal of the kidney generally. Perhaps there is a slight tendency amongst surgeons to prefer lumbar nephrectomy for the common affections. But the whole question can only be decided when we are able to group our cases more accurately, and have a far larger amount of material to judge from than at present.

ARTHUR E. BARKER.

NEPHRITIC COLIC. *See NEPHROLITHIASIS.*

NEPHRITIS, or inflammation of the kidney, is met with in a great variety of forms, from the mildest catarrh to the most destructive suppuration. In surgery we are not often concerned with it as a primary affection, but usually as secondary to some general or local condition. It is not proposed to do more here than give an outline sketch of the simpler forms, as they come under the notice of the surgeon.

Simple nephritis, as distinguished from pyelonephritis and pyelitis, may be either *acute*, *subacute*, or *chronic*. The *acute* form is met with after injuries to the kidney, exposure to cold, the use of over-stimulating diuretics, such as cantharides and turpentine, or too large doses of other irritants, such as the mineral acids, nitrate

of potash, and carbohc acid; it is also met with in various acute febrile states. Besides these exciting causes, may be mentioned one to which considerable attention has of late been directed. This is the reflex irritation of the kidney produced by operations on, or acute inflammations or injuries of, the lower urinary organs. The manner in which this irritation operates, in producing renal hyperæmia, is best explained by the theory of reflex vaso-motor disturbance. The violent stimulus to the nerves of the urethra, penis, or bladder, produces first a contraction of the renal capillaries, followed by great dilatation. The congestion thus arising may be, on the one hand, so slight as hardly to deserve the name of an inflammation, or, on the other, may be deep and persistent. In the first case we have a transient catarrh, in the latter a definite interstitial nephritis. The kidney in the last condition will be found more or less enlarged, darker than usual in colour, and on section engorged with arterial blood, and possibly dotted with small ecchymoses.

The *symptoms* here, whatever the nature of the exciting cause, will usually be the same. In the first place there will be dull aching pain in the affected kidney or kidneys, aggravated by either movement or pressure over the flank. There will also be fever, with malaise, headache, anorexia, and insomnia, sometimes nausea or even vomiting. The attack may have been ushered in by a rigor; the skin will probably be hot, flushed, and dry; the mind is not usually affected. The objective symptoms are found in the state of the urine. This is usually very scanty, or, if both kidneys are affected, there may even be temporary anuria; it is highly coloured or 'smoky,' acid, and loaded with lithates, and deposits a brownish sediment. This, under the microscope, will be found to consist of blood-corpuscles and blood-casts, of urates and renal epithelium. The fluid will probably be of low specific gravity and highly albuminous.

In the *subacute* form, there is only a difference of degree in all these phenomena.

The *treatment* of simple acute nephritis, apart from that of any condition which may have played a part in the production of the disease, is aimed at reducing the work thrown upon the kidneys, and diminishing their acute congestion. The first of these requirements is met by encouraging the skin to act by hot vapour or water baths, with the cautious administration of

diaphoretics and smart purgatives, and by the regulation of the diet, which should be very light, consisting chiefly of milk. The second is fulfilled by local blood-letting over the kidney in sthenic cases, or dry cupping in asthenic cases, followed by hot poultices, and by complete rest in bed and avoidance of exposure. Diuretics are to be avoided, and alcoholic stimulants used sparingly.

The *chronic* form of this disease has a special interest for us here, inasmuch as it is met with in many surgical affections to which it is secondary. Chronic interstitial nephritis may be produced, simply by the continued operation of many of the causes spoken of above, as agents in the acute disease. The most interesting of these, however, for the surgeon is prolonged irritation, either in the bladder or urethra. This irritation may be due to stone or stricture, to villous growth or chronic cystitis, and is capable of producing very profound changes in one or both kidneys. Taking a well-marked case of chronic interstitial nephritis as an example, we may expect to find the affected organ smaller than usual; its capsule does not peel off easily, or may actually adhere closely to the cortex, and leave a granular or broken surface on being separated forcibly. The cortex is more or less reduced in depth, and is granular, toughened, or even almost fibrous on section. The same may be said of the pyramidal portion; the calyces are pale. Under the microscope we see all the evidence of interstitial hyperplasia, with more or less atrophy of the secreting substance.

The *symptoms* of chronic interstitial nephritis are not very distinctive in all cases; still there are some which assist us much if taken with other evidence, and especially the past history of the case. First, the character of the pulse aids us. It is hard and incompressible, and gives the tracing of high arterial tension with the sphygmograph. The muscular vigour and general strength of the patient will be probably much lowered. The urine is usually pale and of lower specific gravity than normal; it is deficient in urea, and often contains albumen and a few casts. In amount it may be normal, but it will probably be somewhat below the average standard.

The *treatment* of chronic interstitial nephritis is general rather than local. The avoidance of rapid alternations of temperature stands first; then, the maintenance of an equable action of the skin by warm clothing, baths, and frictions, and the regu-

lation of the bowels by purgatives. The diet should also be carefully attended to, and all articles tending to over-stimulate or throw much strain on the eliminatory functions of the kidney must be avoided. Every source of irritation in the urinary tract should be removed if possible, but it must be remembered that the use of instruments to this end should be as far as practicable avoided; the passage of catheters, for instance, or operations on the urethra or bladder, being very badly borne in many cases where this condition is present. Indeed, chronic interstitial nephritis is chiefly interesting to the surgeon as one of the barriers to operation on the lower urinary organs. Where any source of chronic irritation has been long present in the urinary tract, it should always be looked for; and any evidence of its presence should be carefully sifted before such an operation is decided on.

ARTHUR E. BARKER.

NEPHROLITHIASIS, or the presence of calculous matter within the kidney, is a very common condition. Owing to some fault in digestion (using the term in its widest sense), or, on the other hand, to some deficiency of energy in the kidney, the amount of organic matter, thrown upon the latter for elimination, exceeds its powers of excretion in solution at some particular time, and a certain quantity is deposited in a crystalline or sub-crystalline form in the organ. It appears probable, however, that without some local morbid condition—e.g. a catarrhal state of the lining of the tubules, pelvis, or calyces—such a deposit will not take place, no matter how concentrated the urine, and many arguments are adduced in support of this view.

The exact point of origin of the earliest traces of renal calculi it is not easy to determine; but it appears probable, from the most recent observations, that they begin to be formed in the renal epithelium. Impaired energy in the cells of the latter, whether it be due to over-exertion and consequent exhaustion, or decay from age, may lead to the accumulation in them of one or other of the crystalline matters met with in calculi. Be this as it may, small concretions are frequently found in the straight tubules, and projecting from the pyramids. These, which are formed of crystals, altered by their suspension in an albuminous medium, are the centres around which the larger stones are formed. According to the condition of the urine in which they eventually sojourn, they will receive

laminated deposits of one or other of the calculous materials. Those most frequently met with in the kidney are—uric acid, oxalate of lime, and phosphate of lime. In the majority of cases, the small concretions pass rapidly into the ureter and bladder, giving rise to no further renal derangement; but, in other cases, the crystals are retained in the tubes or calyces, attached to some roughened spot, and there become aggregated, so forming by gradual accretion the smaller or larger stones with which we are familiar. These are met with at all ages, and in both sexes with about equal frequency. Carbonate of lime calculi have also been found in the kidney, but are very rare. All parts of the organ may be the seat of these concretions, but the urate and oxalate calculi are more likely to be found in its substance than the phosphate and carbonate of lime, which are met with in the pelvis. Calculi of the kidney are mostly irregular in shape, but the greatest irregularity is seen in those lying in the pelvis, where they often form large, branching, tree-like accretions. Where phosphate of lime is deposited, it sometimes forms simply a thin coating over the pelvis of the kidney, without any actual definite calculus. Such a deposit clings closely to the mucous membrane on which it lies, and may be very extensive, or only cover one or more small patches. All renal concretions may be single or multiple, but are more commonly single.

Calculi in the kidney may give rise, on the one hand, to little or no trouble throughout a long lifetime, or to the most intolerable suffering or even rapidly fatal disease. They claim our attention on account of—(1) pain; (2) **HÆMATURIA**; (3) obstruction of the ureter and **HYDRONEPHROSIS**; (4) suppuration due to their presence, with or without **PRO-NEPHROSIS**.

The evidence of the presence of calculi in the kidney is based, in the first place, upon the family and personal history of the patient, and then upon certain subjective and objective symptoms. In many cases, there is a history of the uric acid diathesis in the patient's family for one or two generations, and in his own case, perhaps, for a long time anterior to the date of his present ailment. He may have lived, too, for a longer or shorter time in a 'stone country' himself. He will often give the history of having habitually passed highly acid urine, depositing lateritious sediment on cooling, or may even have voided small calculi from time to time, with or without what is known as **RENAL COLIC**. The symptoms will de-

pend, not so much upon the size and shape of the stone, as upon its situation and the condition of the kidney in which it lies. For it is well known that a large and irregular mass may lie for years within the kidney without giving rise to much trouble, while a small, comparatively smooth, calculus may be a most troublesome inmate of the organ.

Taking the simple cases of nephrolithiasis first, in which there is little or no structural alteration in the kidney, we have to consider certain symptoms, *subjective* and *objective*. Among the former pain stands foremost. This is either local or radiated, or both. When local, it is usually described as constant, dull, aching, or gnawing, but it may be pricking or lancinating. It is subject to exacerbations, often without any assignable cause, but is generally much aggravated by movement, and sometimes to such an extent as to render the patient bedridden. In such cases, the pain can often be traced to the blocking of the ureter by a blood-clot, produced by the movements of the calculus in the pelvis of the kidney. The radiated pain is usually described as localised about the neck of the bladder, or running down towards the groin in front of the thigh, and into the testicle or penis; it has even been observed as low as the foot. Tenderness on palpation over the kidney is another symptom often prominent, but it may be conspicuously absent. Nausea is also occasionally noticed, and that not only on the passage of a stone down the ureter, but also from its presence in the pelvis of the organ. It is also often felt as the result of a blood-clot, from irritation of the stone, stopping up the ureter and causing distension of the pelvis of the organ, or, again, where a clot passes down the ureter slowly.

The *objective symptoms* in simple non-suppurating cases are not many. Among the first comes hæmaturia, which may be very abundant, giving rise to bright red urine, or only cause a 'smokiness' of the secretion. In all cases, however, the blood is thoroughly mixed with the water. Next to this symptom comes frequency of micturition, which is often marked. Then, retraction of the testicle is noticed in a small proportion of cases. Finally, there may be a trace of catarrhal products in the urine, the latter remaining acid. This is a valuable symptom if disease of other parts of the urinary tract can be excluded, and when taken with other evidence.

In *suppurative* cases, or, where there is impaction of a calculus in the ureter, we find, of course, several additional objective

symptoms and a few subjective. Among the latter are rise of temperature, thirst, headache, and anorexia. The rise of temperature is often very regular at night, and may equal two or three degrees. The objective symptoms will be those of pyonephrosis or hydronephrosis, with more or less pus in the urine in the former case. But without either pyo- or hydronephrosis, the kidney may be enlarged by chronic inflammation so as to be felt easily by the hand; or, what is more common, the perinephral fat may be condensed or destroyed by inflammatory irritation due to the stone, and its place may be taken by a thick layer of fibrous tissue, which gives the impression, on handling, that the organ itself is enlarged. In such a case, the position of the organ will probably be somewhat altered, and we shall find it lower and more internal than usual. This is probably due in part to its increased weight, and possibly also to increased muscular contraction of the ureter under the stimulus of inflammation.

Treatment.—During the last few years the treatment of nephrolithiasis has undergone much change. The preventive treatment, in the first place, has improved with the increasing knowledge of the laws which govern digestion and excretion. But where a calculus has actually formed in the kidney, we are no longer satisfied with simply dealing with each symptom as it arises, be it pain, suppuration, or bleeding; but we aim, in suitable cases, at the removal of the directly offending cause—viz. the stone. It is necessary, however, to insist on the exclusion of cases unsuitable for operation. On the one hand, many individuals spend a long life almost or altogether free from pain, in whose kidneys considerable stones are found after death, and, on the other, we often find very small calculi giving rise to the most acute suffering and even danger. Again, facts are accumulating which show that most of the symptoms, ordinarily attributed to the presence of a stone in the kidney, may be present to a perfectly deceptive degree for years, and yet on operation, or after death, no trace of a foreign body be found in the organ or in the bladder. Three chief conditions, then, should be clearly present before the question of operation is entertained, even for a moment:—(1) That the symptoms should be as clear as possible; (2) that the patient's sufferings should be intolerable in spite of all treatment, or that there should appear to be danger from prolonged bleeding or suppuration; (3) that the disease should not have lasted so long as to have damaged the patient's general

health so far as to render the operation a desperate one, and, above all, so long as to risk the functions of the opposite kidney.

If these conditions be fulfilled, we have a choice of three operations—of NEPHROLITHOTOMY, NEPHROTOMY, and NEPHRECTOMY. But in simple cases of nephrolithiasis, in which there is clear evidence of the presence of a calculus and little or none of further morbid conditions about the organ, but where the sufferings are severe, we now almost entirely limit ourselves to the first of these procedures. For it has been abundantly shown, already, that it is quite possible to excise a calculus from an otherwise healthy kidney, with little or no risk to the patient, and with no special damage to the organ. If this be so, nephrolithotomy, and it alone, is the proper operation wherever possible. There are, however, as already stated, cases where all the subjective and objective symptoms point to the presence of a calculus, and yet where none can be found on reaching, handling, and puncturing the organ. Here it is in some cases right to incise the kidney at once, and search the pelvis and calyces for a foreign body, and, if the symptoms have been very severe, to proceed to nephrectomy, even though none be found. The latter operation, however, will doubtless become much rarer as our powers of examination and diagnosis become more developed.

The general treatment of nephrolithiasis, short of operation, will embrace careful attention to diet, the use of baths, and friction of the skin in order to promote its healthy action, and the regulation of the bowels. The liver should be particularly attended to, the mineral waters of Friedrichshall and Rubinat being used with much benefit. Warm clothing and regular exercise should also be enjoined.

Prognosis.—Lithiasis of one kidney does not appear to shorten life. A patient may develop small calculi in the kidney, and continue to pass them by the ureter for years, without any decided impairment of health. It is only when the foreign matter is retained in the organ from any cause, and begins to produce secondary changes there, or the retention of secretion or of pus, that it becomes really dangerous. And even when both kidneys produce calculi which do not lodge in them, they may for a long time, if not indefinitely, remain adequate for all the wants of the system. But when calculi commence to be retained on both sides, they indicate a vice which will probably lead to grave complications before long. There appears, however, to be no

very decided tendency for calculi to appear on both sides at the same time; they are frequently unilateral. ARTHUR E. BARKER.

NEPHRO-LITHOTOMY, or the removal of a stone from a kidney not sensibly enlarged and with no evidence of accumulation of pus, is one of the most recent achievements of modern surgery. With the improvements in diagnosis of renal disease, we have learned to recognise, in many cases, the presence of a calculus, either in the pelvis or substance of the organ, *before this has been followed by suppurative irritation*. If, under these circumstances, the foreign body be removed, there is an immense gain to the patient. The dangers of suppurative pyelitis are prevented, suffering is relieved, and the organ, often comparatively healthy, is preserved to the economy. This operation was first performed on definite principles by Mr. Morris in February, 1880, and since then has often been repeated, with equal success, by other surgeons.

It is necessary to insist on the difference between this procedure and that of ordinary nephrotomy or incision into a suppurating kidney. This is quite distinct as to principle, aim, and prognosis. To incise the loin, and subsequently a sound organ, in order to remove a foreign body whose presence is causing certain subjective symptoms only, is totally different from cutting into the perinephral tissues in a state of inflammation, and opening up the kidney itself in order to give exit, not only to the calculus, but also to the products of inflammation, the result of its prolonged sojourn in the organ. And the prognosis of the two operations is quite different. In the first instance, though it may be more difficult to find the stone, the incision, being made in comparatively healthy tissue, heals readily in many cases; in the second, a freely suppurating cavity having been opened through more or less diseased tissues, many risks are run connected with septic infection, and a fistula in the loin is almost invariably left, a condition by no means devoid of danger, and giving rise, in all cases, to much discomfort. Both operations have their place, and their own special advantages; but they must always be kept apart, as essentially different.

The procedure itself is not difficult, but there are still great obstacles to its general employment. On the one hand, all the symptoms of stone in the kidney may be present, and yet, on reaching the organ by incision through the soft parts, no evidence of its presence may be detected, either by

the most careful palpation on all its aspects, or by acupuncture to the fullest extent, although the stone is actually in the organ. On the other hand, there are conditions beside renal calculus, producing symptoms which, for the present at all events, we are unable to distinguish from those of undoubted nephrolithiasis. *See* NEPHRALGIA. Both these facts have been established by operations on the living, and by observation, during life, of cases which have afterwards become the subjects of post-mortem examination. It is fortunate, however, that the same experience has also established the fact that exploration of the kidney by direct palpation, acupuncture, and even incision into its substance, is a procedure attended with very little risk if every precaution against septic infection be observed.

The operation itself is essentially the same as that of NEPHROTOMY, except that the point of incision into the kidney is determined by the situation and size of the stone; also, perhaps, there may be more difficulty in reaching the unenlarged organ behind the ribs, than in those cases for which nephrotomy is usually performed, where the kidney is mostly increased in size and has descended somewhat in the abdomen. But, on the other hand, there may here be less difficulty in examining the surface of the organ, on account of the absence of perinephral irritation, with consequent destruction or induration of the fatty and areolar tissue surrounding its capsule. In some cases in which nephrolithotomy is performed, the wound in the kidney remains open for a long time, giving rise to urinary fistula in the loin; in other cases it heals up rapidly and finally, any discharge from the interior of the organ finding its way down the ureter, and this often for a long time after the lumbar wound has quite closed.

The *prognosis* after this operation is very favourable. Up to the present all the cases of true nephro-lithotomy recorded have proved successful. It is important, as already stated, to remember this, and to distinguish between these results and those of nephrotomy and nephrectomy for more advanced disease. Many lives will be saved and much suffering averted by recognising this immunity from risk of nephro-lithotomy; and the necessity for early diagnosis of renal calculus and treatment by this operation, before such structural changes have taken place in the kidney as to render one or other of the more severe measures necessary.

ARTHUR E. BARKER.

NEPHRORAPHY, or the stitching of the kidney to the posterior abdominal wall, in cases of mobility of the organ, accompanied by severe symptoms, is an operation performed many times of late years with considerable benefit, but not often enough as yet to enable us to form a definite judgment upon its proper position as a surgical procedure. Up to the present time, however, it has been shown to be without risk, and the only point which can be urged against its performance is, that it is not always followed by permanent fixation of the organ and complete relief of suffering. The operation is only suited to those cases of movable kidney in which there is no mesonephron. *See* MOVABLE KIDNEY. Should the latter be present, it would be impossible to perform nephroraphy without injuring the peritoneum; but where the kidney simply slips about in the loose perinephral fat there is little danger of this, and the organ can be reached easily.

The operation consists in cutting down upon the kidney by one of the usual incisions for reaching the organ in the loin (*see* NEPHROTOMY); then the fatty capsule is drawn into the wound and stitched with eight or ten catgut sutures to its deeper edges. Besides these stitches, one or two are passed through the abdominal wall in front of the incision, and then through the cortex and proper fibrous capsule of the organ, which is pushed backwards by an assistant, to return through the abdominal wall behind the incision. These last sutures are fastened with buttons, and draw the kidney itself backwards towards the wound. A large drainage-tube having been inserted, the wound is closed with a few silk or catgut sutures. Very little bleeding ought to take place at any part of the operation, but some is seen on piercing the cortex of the kidney. This soon ceases, and if the wound be treated, as it should of course be, on the strictest antiseptic principles, the blood will have no ill-effect on the wound.

The drainage-tube may be left for a week or ten days, and the small amount of irritation necessarily produced will probably increase the firmness of the adhesions between the kidney and abdominal wall behind. The after-treatment consists in keeping the patient in the recumbent position for a considerable time after the operation, in order that the weight of the kidney may not stretch the new adhesions. The bowels should also be regulated. Subsequently, when the patient gets up, an abdominal belt should be worn, furnished with a pad, pressing gently, but firmly, over the renal

region in front. But, even with this, the patient should avoid all but the gentlest exercise for a long time after the operation.

It appears probable that we shall hear more of this procedure in the future, as it seems to offer many advantages over other modes of treatment in suitable cases, and to involve little risk. Writing in June, 1883, Dr. Newman says he had collected eight cases in which this operation was performed, and among these there were no deaths: at least five were cured of their troubles, the other three were too short a time under observation to judge of its effects.

ARTHUR E. BARKER.

NEPHROTOMY, or simple incision into some part of the kidney, is performed for a variety of conditions, chief among which are calculous or tuberculous pyelitis, pyo- and hydronephrosis. It is an operation of some antiquity, but, amongst the older surgeons, was performed only when the collections in the kidney or its pelvis had made their way very close to the surface, and were about to burst externally. Recently, the operation has been revived and developed, and is now performed at a much earlier stage of disease than formerly. Thus done, and with all the improvements of antiseptic surgery, nephrotomy is a measure attended with but little risk. It is now almost always performed at the same spot—viz. midway between the last rib and the crest of the ilium, and at the outer edge of the erector spinæ muscle. The incision through the skin and soft parts varies with the views of different operators. Sometimes it is vertical, along the outer border of the erector spinæ, for two or three inches; sometimes it is transverse, or obliquely downwards and forwards for the same length, or a combination of the vertical and oblique incision is adopted. But whatever line is chosen, the central point of each is practically the same for all ordinary conditions. Supposing the operation to be for calculus in the kidney, without much or any enlargement of the organ—a condition in which greater difficulties are met with than in others—the steps of the procedure are as follows.

The colon is carefully unloaded by enema. The patient is then placed on the opposite side, with a thick sand-bag under the flank, so as to make the side operated on as prominent as possible. The incision preferred by the writer is oblique, parallel to and a little below the last rib; it should sever the skin and superficial fat at once. The muscular layers are then divided, on

a director, until the posterior tendon of the transversalis muscle or fascia lumborum is reached. When this white structure is divided sufficiently, all the soft parts are held asunder with broad spatulæ, and then, the surrounding fat being carefully torn through with the finger or probe, the kidney is found embedded in it. In this dissection one or two arterial twigs may be cut, but are easily secured in the clip-forceps. The kidney may now be opened up in various ways, but is best incised longitudinally with a narrow-bladed scalpel, the organ being pushed toward the lumbar wound by the hand of an assistant pressed against the abdominal wall. When an opening has been made with the knife large enough to admit the finger, the wound may be enlarged by simple dilatation with the latter, or by the blades of a forceps thrust into it and expanded. This opening up of the organ will of course in many, if not all, cases be preceded by the other means of ascertaining its state, such as palpation, with the finger on both front and back aspects, and by acupuncture, and may be done boldly when we have by these means satisfied ourselves of the presence of a stone. But, even in those cases where the latter is not detected by these means, but there is still strong evidence of its presence from the subjective symptoms, &c., it will be proper to incise the pelvis from within outwards, and explore it well with the sound or finger. In such cases, too, the substance of the organ may be incised without much risk, if the cut be made steadily in either of the planes of the uriniferous tubules; but for calculus of the pelvis incision of the parenchyma is unnecessary.

There is, usually, smart bleeding when the cortex is cut into, but this will soon cease, as a rule, under pressure, either directly applied, as with a sponge, or indirectly, through the abdominal wall. If it prove too troublesome, the wound should be packed with antiseptic wool or a sponge wrung out of a strong antiseptic solution, the abdomen being firmly compressed with a bandage. In all cases, the incision in the abdominal wall should be carefully drained by a tube reaching quite down to the kidney, in some cases passing well into the organ. This tube will have to be kept in for a longer or shorter time, varying with the needs of the case. If it is one of hydro- or pyonephrosis the tube should be long, and provided with a rubber shield to prevent its slipping into the sac. The whole operation and the after-treatment of the case, whatever its nature, should of course be con-

ducted on strict antiseptic principles. Either silver or silk stitches may be used for the lumbar wound; the writer inclines to the use of the latter.

Prognosis.—It is impossible to give any reliable statistics showing the relative dangers of nephrotomy, the operation having been done for so many different conditions. But it may be fairly said that *per se* the procedure is not attended with any special dangers in most cases. Unfortunately the diseases for which it is performed are usually very advanced, and the operation is too often undertaken merely as a palliative, and if the patients succumb, the result is recorded against nephrotomy. Increased knowledge of the possibilities of renal surgery, and improved power of diagnosis will no doubt effect a reform here. Renal disease will be recognised much earlier than hitherto, and will be submitted to the surgeon, with confidence, at a stage in which the risks of operation are immeasurably less and the prospect of permanent benefit far greater. Eventually nephrotomy will probably become a rare operation, while nephro-lithotomy for disease at its earliest stage will proportionately increase in frequency.

ARTHUR E. BARKER.

NERVE-AVULSION. — Nerve-avulsion denotes the tearing out of the trunk of a nerve, as far as possible, from the bony foramen it passes through. This operation is resorted to as a last resource where previous NEUROTOMY or NERVE-STRETCHING has failed to give more than temporary relief in cases of severe neuralgia. The operation has almost invariably been performed on one or other of the branches of the trigeminal nerve, in the following way.

Operation.—The patient having been deeply anæsthetised, a vertical incision is made in the course of the nerve, and just over the bony foramen through which the trunk leaves the skull. The nerve is then freed from its peripheral attachments, is grasped in strong forceps—e.g. torsion-forceps, &c.—and wrenched out as far as possible. When the bone is left untouched, it will be found that the nerve almost invariably breaks off at the external orifice of the canal, the reason being that it is tightly fixed to the margin of the hole by very tough fibrous bands, which pass from the epineurium to the periosteum.

When the necessities of the case (e.g. return of the pain, &c.) demand that the rest of the nerve should be excised, the bony canal has to be opened up. In the case of the infra-orbital nerve this may be

done in two ways:—(1) The soft tissues filling the orbit may be detached along the lower border of the same and held up by Wagner's retractor, which is spoon-shaped; the nerve will then be seen running along the floor of the orbit, covered by a thin plate of bone and periosteum. The advantage of exposing it in this situation lies in the fact that the anterior dental branches are given off from the nerve while it remains in the canal; so that if the neuralgic pain is referred to the alveolar border of the jaw, it is obviously necessary to remove the whole nerve. (2) In very obstinate cases, it is advisable to remove not only the infra-orbital nerve but Meckel's ganglion also, as far as possible. This has been done by trephining the wall of the antrum and following the nerve back to the ganglion, which is then torn out. In this way the posterior dental branches are removed and, when thoroughly performed, anæsthesia of the palate obtained—a very important result, as the palate is frequently the starting point of the pain.

The inferior dental nerve is best reached at its peripheral extremity by depressing forcibly the angle of the mouth, while an incision is made parallel to the gum and just opposite the canine tooth, at the line of reflection of the mucous membrane from the jaw. The soft parts are then separated from the periosteum until the mental foramen is reached, and the fibres of the nerve felt issuing from it. The nerve-trunk should be exposed, and a loop of silk knotted on it. The outer margin of the foramen is next broken open with a sharp chisel and small bone-forceps, each blade of which is pyramidal in shape, so as to allow of either being inserted into the canal for the desired distance (usually an inch to an inch and a half), and the nerve is then lifted up by the ligature from its bed and removed as far as possible.

The nerve can be reached from inside the mouth also, where it enters the upper extremity of the dental foramen, the guide being the small bony spine on the lower margin of the same. The internal pterygoid is held aside with a retractor, while the nerve is freed for some little distance with a blunt instrument. It can also be reached, at the same point, by trephining through the ramus of the jaw and laying the nerve bare *in situ*.

The wound in all cases should be mopped out with strong carbolic acid solution (1-20), or chloride of zinc 40 gr. to f3j., then dusted with iodoform, and plugged with iodoform wool until granulations spring up from the

bottom, when it is to be frequently irrigated with weak Condy's fluid or sanitas.

The anæsthesia produced will gradually diminish to a very considerable extent, but the relief is always permanent where the cause is clearly shown to be neuritis. In all cases, deep **HYPODERMIC INJECTIONS** of ether, &c., should be attempted before operating. See **NEUROTOMY** and **NEURECTOMY**.
VICTOR HORSLEY.

NERVE-SECTION. See **NEUROTOMY**.

NERVE-STRETCHING.—By *nerve-stretching* is understood, either the bloodless operation of stretching the nerve-trunks in a limb by forcible extension of the distal joints, or the operation of laying bare a nerve, lifting it from its bed, and pulling it either in the direction of its course or at right angles to the same. Under the term nerve-stretching is also often included **NERVE-AVULSION**, an operation in which a nerve-trunk is completely torn out of its bed, as far as possible.

The following paragraphs relate only to nerve-stretching as defined above. The method of operation will be discussed first, next the anatomical changes and physiological effects it produces, while its value as a therapeutical agent will be given in conclusion.

1. The *bloodless operation* is performed thus: The patient being anæsthetised, the limb is first fully flexed at the proximal joint (e.g. the hip), the middle joint (e.g. the knee) is then slowly but firmly extended, and, when at the point of extreme extension, the distal joints are also extended. (Of course in this case the ankle will be forcibly 'flexed.') This state of tension is to be kept up for not less than from ten to fifteen minutes, and then the limb should be thoroughly shampooed, firm pressure being directed centrally, for another period of ten or fifteen minutes. The only point of risk to be mentioned is, obviously, the possibility of the vessels being diseased; and it is to be noted that the tension on a diseased popliteal artery is not much lessened by previously flexing the hip-joint.

2. The *cutting operation* is performed in the following way:—The patient being anæsthetised, a free incision is made in the direction of the nerve, and vertically over it. The superficial structures are divided to the same extent as the skin, and the muscles separated and held aside with retractors; the nerve will then be found lying beneath a layer of fat, and surrounded by a quantity of loose connective tissue, which forms

a 'false' sheath. This fatty tissue is now to be freely incised, until the epineurium or proper sheath of the whole nerve-trunk is exposed, contrasting by its shining white appearance with the surrounding yellow fatty tissue. The nerve should be freely isolated by knife and forceps, so as to admit of the forefinger being passed beneath it; if it is lying at the bottom of a deep wound, or if it is a small nerve, it should be gently lifted by a blunt hook until it can be grasped between the finger and thumb; care is to be taken that the hook is not used with force, otherwise many nerve-fibres will be damaged by the pressure of the instrument. See **NEUROTOMY**.

The nerve being firmly held between the finger and thumb, is then to be steadily pulled for about five minutes, first centrifugally, and then centripetally for a like period of time. The tension must be gradually applied and kept constant the whole time, while all jerks (the force of which is unknown) are to be avoided. The actual amount of force, with which it is advisable to pull, varies from a maximum of thirty pounds for the sciatic nerve to half a pound for the supra-trochlear. The amount of force must necessarily vary with individual development and the state of the nerve (Marshall). It will now be found that the nerve is loose and elongated, owing to its elasticity being relatively very imperfect.

The extension of the nerve is mainly produced by the nerve being drawn tightly along the length of the segment of the limb in which it lies, since in the ordinary position of a limb at rest, and even in the position of extension of one joint, the nerve-trunks are never taut, and when the limb is flexed they exhibit a wavy border, showing their complete relaxation.

The nerve is now replaced in the bottom of the wound; any bleeding vessel is to be ligatured, the wound perfectly dried, and the sides then brought together by a supporting silver suture or two, passed deeply through skin, fascia, and muscle, and crossing about half an inch in front of the relaxed nerve. The cut edges are then to be united with numerous catgut or horse-hair sutures, and a small drainage-tube inserted at the dependent end of the wound. The whole operation should be performed with strict antiseptic precautions, and healing obtained by the first intention; with this view, the drainage-tube in the largest wound (if perfectly aseptic) may be left out on the third day, and a large dry dressing with proper pads, &c. applied, and left on

for a week or ten days. Restriction of movement in the limb by a splint will be found practically very useful in ensuring rapid union of the wound; indeed, in cases of locomotor ataxy and other instances where the parts are deprived of the normal trophic influence of the central nervous system, this precaution must never be omitted.

3. *After-treatment.*—After the bloodless operation, the patient should be kept quiet in bed for a day or two, and then allowed to exercise the limb gradually, shampooing being performed daily. After the cutting operation, the same treatment should be adopted as soon as the wound is absolutely healed. This obviates the possibility of cicatricial bands fastening the cicatrix to the sheath of the nerve, a condition of things which is productive of considerable discomfort to the patient, by causing twinges of pain when the hip is flexed or firm pressure made in the neighbourhood of the scar.

4. *Effects of Nerve-stretching.*—(a) *Anatomical Changes, Macroscopic.*—It has been shown that when a nerve (e.g. the internal popliteal) is stretched by a weight below 10 lbs., the tension is thrown almost entirely on the fibrous sheaths of the nerve, viz., the loose epineurium binding the primitive bundles together, and the denser perineurium which ensheaths each primitive bundle. Also, all the nerve-fibres are straightened, and only altered, as described below, when the pressure reaches to more than two-thirds of the breaking strain. As a natural consequence of the tension the blood-vessels are compressed and emptied, while the lymph-spaces are absolutely obliterated and their contents driven out into the efferent trunks. It is very clear then, that if there is any inflammatory tension in the nerve, this must be got rid of by such a thorough compression of the vessels and connective tissues. (The 'bone-setters' in Turkey cure neuralgia of nerve-trunks by exerting very powerful and hard pressure along the course of the nerve, from the periphery towards the central end.)

Microscopic.—Harless and others have shown that the myelin sheath of the nerve-fibres exhibits transverse ruptures of every degree; while in cases where very severe tension has been employed, or at the point where a hook has been applied for the purpose of forcibly lifting a nerve from its bed, the myelin has been found to be broken up and aggregated in small droplets within the neurilemma. The axis-cylinder in some specimens appears attenuated and nodose,

but is very rarely injured. Provided the nerve is not torn across, regeneration always takes place.

(b) *Physiological Effects.*—These may be considered under two headings—(a) Effects on the conducting power of the nerve-fibres; (β) effects on the nerve itself, including the explanation of the beneficial effects of nerve-stretching in neuralgia, sciatica, &c.; (γ) effects on the central nervous system.

(a) *Effects on Conduction.*—A mixed nerve contains: (1) motor fibres; (2) sensory fibres; (3) vaso-dilator fibres; (4) fibres (possibly identical with 1) conveying trophic influences; (5) secretory fibres.

The effect of stretching a nerve gently is to heighten the conducting power of all these fibres, so that a limb, the main nerves of which are moderately stretched, exhibits slightly increased mobility, slight hyperæsthesia and marked increase of reflex excitability, increase in blood-supply and increase in nutrition, coupled with rise of temperature.

A stronger pull on the nerve will change this hypertonic into a hypotonic state, for then every function of the fibres, except that of movement, will be obviously diminished, and the first group of fibres to show this change is the sensory set, the result being diminution of reflex excitability, hyperæsthesia, and ultimately anaesthesia. A still more severe pull will affect the efferent conducting paths in the same way; thus, slight paresis up to paralysis may be produced, and at the same time trophic ulceration with loss of digits, and œdema of cellular tissues (most probably from vasomotor paralysis) may be seen. These profound trophic changes are not seen in man, owing to the fact that the amount of force required to produce them would be obviously unjustifiable. In fact, if the operation is performed for the relief of pain (e.g. in sciatica, tabes dorsalis, &c.), although half-measures are much worse than useless, still no paralysis beyond that of sensation, and that slight, should be produced in the part supplied by the nerve. The amount of force necessary to produce this may be put down as one-third of the breaking strain, as a rule. In every case, recovery of power of sensation, &c., will be obtained if the nerve is not divided, and if proper after-treatment is adopted.

(β) *Effects on the Nerve itself as an Organ.*—These are rather questions of anatomy, and have been discussed above, but one point of pathological interest has not been referred to, and may be mentioned here. It had been known for some time that

a person could accurately localise touch and pain in a nerve-trunk, and that the pain in neuralgia, sciatica, &c., was referred, as a rule, to the trunk of the nerve, which was found to be tender on physical examination, &c. Mr. Marshall assumed the existence of *nervi nervorum*, pressure on which from inflammatory exudation, &c., would explain the localised symptoms just described; and at the same time he showed that nerve-stretching would so damage these *nervi nervorum* as to diminish their conducting power. The writer has found that nerve-fibres and sensory nerve-endings are present in the sheaths of nerves, so that the anatomical basis of the above theory is supplied. It will be obvious that a very slight increase of vascularity, and consequent oedema, will cause very urgent symptoms by pressing on such nerve-endings enclosed within a firm sheath like the epineurium, and more especially in nerves (like the inferior dental, &c.) which lie in hard inextensible bony canals.

(γ) *Effects on the Central Nervous System.*—It still remains a question whether the extreme stretching of a nerve does produce any real effect on the spinal cord or base of the brain. It can very easily be shown, by exposing the spinal cord within a very short time of death, long before rigor mortis has set in, that, contrary to what has been frequently stated, there is no mechanical effect whatever produced on the nerve-centres by stretching peripheral nerves; the simple fact being that nerves are so fixed by fibrous bands in the bony foramina of the spine and skull, as to preclude the possibility of the least movement being transmitted. There then remains the possibility of the mechanical irritation of the nerve-fibres causing changes (functional) in the nerve-centres. Brown-Séquard and Quinquaud have asserted that, given anæsthesia by hemisection of the cord, this can be removed by nerve-stretching. This requires confirmation, as Prevost has obtained simply negative results in repeating the experiments. There certainly appears to have been produced, in guinea-pigs, a condition of greatly exaggerated irritability of the motor centres, leading to convulsions, &c., but very little can be argued from guinea-pigs direct to man, especially on this matter.

5. *Nerve-stretching as a Therapeutical Agent.*—It will be best, perhaps, to enumerate the different diseases in which nerves have been stretched with distinct advantage, and under each heading to mention the principal points which require special attention. It must be remembered that the estimates

given, of the percentage of cases in which relief was afforded, are necessarily rough and inaccurate, owing to (1) cases being published too early, and (2) cases of non-success being omitted from public records.

A. *For Abnormalities of Movement.*—

(a) *Spasms.*—Motor nerves have been stretched for spasmodic contractions of voluntary muscles with variable success, probably in about 50 per cent. of all cases. The cases should, however, be arranged in at least two groups—viz. spasms caused by old injury to nerve-trunks (Nussbaum's classical case is a good example), and spasms in which it is at present doubtful whether the irritative lesion is in the nerve-trunk or nerve-centres. As might be expected, the percentage of cures is very high in the first class and very low in the second. A common example of the second class is facial tic or *tic convulsif*, in which case, the facial muscles are affected with twitchings commencing insidiously. In these cases, the facial nerve has been exposed by an incision opposite the lower end of the parotid gland, and the nerve stretched on a small blunt hook. As a necessary result facial paralysis ensues, but as this clears up, the spasms tend to return, from which it would appear that the disease is usually of central origin. Putnam found that in a healthy dog eight pounds' pull was sufficient to paralyse; it is very probable that five pounds is adequate for the human being. He also makes the valuable and practical suggestion that, when nerve-stretching is undertaken for the relief of spasm, the patient should be preferably anæsthetised with ether, so that, if necessary, the effects of the anæsthetic may be got rid of during the operation, in order to see the effect of the latter on the affection. Reflex spasm, such as blepharospasm accompanying attacks of neuralgia, must of course be treated by stretching the afferent sensory nerve. See FACIAL SPASM.

(β) *Contracture.*—Wryneck (Billroth) and other instances of contracture in cases of peripheral lesion have yielded to nerve-stretching, but many cases have failed as soon as the conducting power of the nerve has been restored. In cases where the seat of the lesion is doubtful, nerve-stretching should be tried, as possibly productive of good.

(γ) *Tetanus.*—This condition has frequently been treated with nerve-stretching (45 times, Marshall, 1883), but with so small a proportion of successes (14), as to leave it perfectly open whether the good results were not simply cases of ordinary recovery by other means which were em-

ployed at the same time (e.g. Calabar bean, chloroform, &c.). Since we thus get information of very doubtful value from the records of empirical treatment, and since the pathology of tetanus is so obscure, nerve-stretching in this affection cannot be detailed at greater length here, but it may be worth while to mention that the successful cases appear to have been those in which the worst symptom was trismus and not opisthotonos.

(δ) *Reflex Epilepsy*.—In some cases of epilepsy (Nussbaum, &c.) the attack is preceded by violent pains, localised distinctly in different nerves, and, in these cases, very marked relief (amounting to cure in several instances) has been obtained by stretching the nerve-trunks thus indicated. Possibly, those cases in which an attack can be warded off by tightly ligaturing the limb in which the prefatory symptoms appear, could be similarly benefited.

(ε) *Paralysis*.—Paralysis of movement, in cases where a nerve-trunk has been damaged but not divided, have been relieved by lifting the nerve from its bed, freeing it from its attachments, and gently stretching it. The operation has been performed in cases of paralysis from central lesions, with the obvious result of discredit to the operation and operator. Motor inco-ordination in cases of locomotor ataxy is said to have been improved by nerve-stretching; but this requires confirmation, especially as several cases of motor inco-ordination thus relieved do not appear, from the clinical records, to have been genuine cases of ataxy.

B. *For Abnormalities of Sensation*.—

(a) *Hyperæsthesia*.—Just as in the case of disturbances of movement, those cases of aberrant sensation which are due to direct injury, &c., of the nerve-trunk are those which are most relieved by nerve-stretching. Hyperæsthesia, however, may be due to central causes, capable of relief by operation where diagnosis is possible. In stretching nerves for the relief of pain, it is to be remembered that although it must be thoroughly done, still less force is required than when disturbances of movement (e.g. spasms) have to be treated. A second point of considerable practical importance is the possibility of the pain disappearing *gradually* after the operation, in consequence, no doubt, of the gradual absorption of fluid, &c. It frequently happens that the patient experiences some pain (almost always much mitigated) for several days, but cure is ultimately certain if the operation is thoroughly carried out.

(β) *Neuralgia, Sciatica, &c.*—The causation of the pain in these cases has already been discussed, and after ordinary means have been exhausted (e.g. counter-irritants, anodyne applications, deep injections, &c.), nerve-stretching, or, in the case of a purely sensory nerve, nerve-avulsion, will almost certainly result in cure, since the percentage of successes appears, at the lowest estimate, to be 74 per cent. (Marshall). The special points in connection with nerve-stretching for neuralgia and the pathology of the affection have already been discussed, so that no more need be said here on the subject, save that occasionally a tumour (psammoma) may grow in the membranes covering the long roots of the nerves in the spinal canal (Marshall).

(γ) *Lightning Pains (Tabes)*.—As locomotor ataxy often exhibits peripheral lesions and symptoms, it is not surprising that the lightning pains in that affection have been considerably relieved by nerve-stretching. Owing to the low trophic level of tabetic tissues, special attention must be paid to the wound in these cases, and the condition of the nerve noted before it is pulled. The relief from the pains varies in duration considerably in different cases, but always appears to have been gratefully appreciated by the patient.

(δ) *Anæsthesia*.—The relief of anæsthesia by nerve-stretching has been employed, with especial success in cases of anæsthetic leprosy, by the British surgeons in India. Lawrie published 30 cases, all successful; in fact every case appears to have been so. *Nerve-splitting* has also been found of service, especially where the nerve has become nodose and thickened.

C. *For Abnormalities of Nutrition*.—In 1881, Dr. Bastian caused the sciatic nerve to be stretched to improve the state of nutrition, in a limb the seat of infantile paralysis. The effect was to markedly increase the temperature and colour of the part, and apparently improve the state of the tissues.

VICTOR HORSLEY.

NERVES, Injuries of. — SECTION.—Like all other parts of the body, nerves may be injured in various ways; of these, section by a sharp cutting instrument, such as a knife, is at once the most common and simple. The changes that occur in the nerve-ends after division may be shortly described as follows. The whole of the peripheral portion undergoes degenerative changes in its entire length and distribution. The white substance of Schwann becomes segmented and collects in globules of

varying size within the sheath; finally, the whole of the myelin is destroyed. The axis cylinder splits into numerous longitudinal fibrils, and is gradually completely disintegrated. The nerve, as such, is entirely destroyed within four or five weeks.

After this complete degeneration, regenerative changes occur in the peripheral extremity, independently of its reunion with the proximal end. The nuclei of the sheath of Schwann multiply, and, after a time, unite to one another so as to form new axis-cylinders. Around these the myelin sheath is subsequently formed, but seldom attains the natural dimensions. The length of time required for regeneration of the peripheral end is not certainly known, but the writer has seen new nerve-bundles in the peripheral end six months after section, and is inclined to think that a further period of a year or more frequently elapses before regeneration is nearly complete. It is probable that regeneration is more rapid in young subjects than in old; and it is certain that union with the proximal end materially hastens regeneration.

The changes occurring in the proximal end are, unlike those of the peripheral, strictly limited in their extent, being confined to that portion of the nerve immediately above the point of section; according to some authors, to the next node of Ranvier. In this limited portion of nerve the same degenerative changes occur that have been described as affecting the whole peripheral end, but regeneration is much more rapid. The most noticeable condition of the upper end is the bulbous enlargement, which develops immediately above the point of section within a few weeks of the injury, and which is never met with in the nerve below the point of section. This bulb, which is, roughly speaking, about twice the diameter of the normal nerve-trunk on which it is situated, and oval in shape, is generally matted to the surrounding tissues, and feels very tough and resistant to the fingers. On section, numerous nerve-bundles may be seen, and a microscopic examination will show that the bulb in question is made, not only of fibrous tissue, but also of nerve-tubules, smaller in size than is natural, with a proportionately small myelin sheath, and collected into smaller bundles than are those of nerves in a normal condition. These tubules are either persisting ones, which have altered in size on account of the pressure to which they have been subjected by the dense fibrous tissue, or else new tubes in process of development.

The Union of the Divided Nerve is brought about by a gradual development of new axis-cylinders from the nuclei of the sheath of Schwann, in both the proximal and peripheral ends, forming a uniting medium through which, when perfected, nerve-currents may be transmitted. Whether union will occur in any individual case or not, depends much upon the amount of separation of the divided ends. When these are maintained in close contact and in good apposition, union is both more rapid and more perfect than in the absence of such conditions; yet, even when closely apposed union may fail. If, on the other hand, there is wide separation of the divided ends, and especially if muscle or scar-tissue intervene, union will most likely not occur at all, and in any case will be long delayed. But, though delayed, union may occur even after excision of as much as two to three inches of a nerve-trunk.

The changes that occur in the parts supplied by the divided nerve are many and various. They affect mobility, sensitiveness, and nutrition.

The muscles supplied by the divided nerve are at once paralysed, and remain in this condition so long as reunion is delayed. Not only are they paralysed, however; they also rapidly waste and degenerate. The atrophy of the muscle is much more than can be accounted for by simple want of use, and is infinitely more rapid and complete. It is accompanied by degenerative changes in the intimate structure of the muscular substance, which becomes the seat of fatty change. Within three or four months the muscles have practically disappeared; and not only does the affected muscle diminish in bulk, it also becomes actually shorter, and may thus cause considerable interference with the freedom of action of other muscles. Notwithstanding their complete atrophy, the muscles become entirely regenerated if union of the divided nerve ensues.

The electrical reaction of the muscles, after section of their motor nerve, is a point of some interest and importance. Within twenty-four hours of the nerve-section, their faradic irritability begins to diminish, and within four or five days is completely lost. In the first day or two after the nerve-injury the galvanic irritability may be increased, but is more frequently not appreciably altered. After this time it gradually diminishes, and in the course of three or four weeks the strongest current fails to produce any contraction. It is during and before this period of diminishing galvanic irritability

that the 'reaction of degeneration' becomes marked. Normally, the kathodic closure contraction of a healthy muscle is greater than the anodic closure contraction. After nerve-section, when degeneration sets in, the anodic closure contraction first becomes equal to, and then greater than, the kathodic, a reaction which indicates degeneration of muscle and nerve, and is therefore a valuable diagnostic sign. After union of the divided nerve has taken place, voluntary power in the previously paralysed muscles returns before faradic or galvanic irritability. The patient may be able to use the muscle for many months before it will contract on application of the electric current.

Loss of Sensation.—Supposing the divided nerve to contain sensory fibres, sensation will be more or less impaired after injury. In most cases complete anæsthesia results, the patient losing all sense of touch and pain, of heat and cold. In other cases, and especially where the part is supplied by nerve-filaments derived from more than one trunk—e.g. the ring finger, which is supplied by both the median and the ulnar nerves—more or less sensibility may persist.

In testing the amount and extent of impaired sensibility, it is necessary to be very careful. Examination of a supposed anæsthetic area should always be made in such a manner as to exclude the possibility of exciting sensory impressions through the medium of neighbouring nerves. Thus, if a finger be pressed or pushed, the patient may perceive through his 'muscular sense' that it is being touched. Or, if the supposed anæsthetic area be tested by the surgeon gently rubbing it with his finger, the vibrations conveyed to the neighbouring healthy nerves will correctly convey tactile sensations. In order, therefore, to avoid being misled, all examinations should be conducted with as little interference as possible with neighbouring parts. The point of a pencil is as good as anything for testing the sense of touch; and the surgeon should notice not only whether the patient can *feel*, but whether he can also correctly *localise* his sensations.

Trophic Changes.—The alterations in the nutrition of the paralysed parts is of much importance. It has already been mentioned that the muscles not only atrophy, but also degenerate. The skin is liable to be attacked in various ways. In some cases there is not much alteration, but in most the surface becomes smoother than is natural, and occasionally, in addition, shiny and glistening, the papillæ appearing to be obliterated. Eruptions of eczema, herpes, or acne may result.

In many cases ulcers appear in the anæsthetic area, and are frequently due to injury of some kind or another which, on account of its painlessness, has passed unnoticed by the patient. Sometimes, however, these ulcers occur while the part is completely protected, and must then be attributed to interference with the trophic nerves. When protected, these ulcers will generally heal, though they may be slow to do so.

In addition to ulcerations, local gangrene may result from nerve-injury—e.g. the finger-tips may be destroyed; the gangrene is of the dry variety. Painless whitlows, with loss of the nails, are also not uncommon. The hair of the affected area frequently falls off, and in other cases becomes brittle and stumpy. The nails may be cast off entire, or may become fibrous and brittle, very curved, ridged, and furrowed. Their appearance is often very characteristic.

Disease of the Articulations.—The joints supplied by a divided nerve generally suffer in proportion to the affection of the soft tissues. An interval of considerable length may intervene between the nerve-injury and the joint-disease, but, in some cases, the latter commences within a few days of the former. The pathological processes that occur are not, as a rule, in any way different from those met with in acute rheumatism. There is the same synovitis with exudation of plastic lymph, the same tendency to affection of the fibrous tissues of the articulation, and, as in acute rheumatism, the inflammation may entirely resolve. Fibrous ankylosis, is, however, much more common after nerve-injuries than in simple rheumatism, and, indeed, may almost be said to be the rule rather than the exception. The writer has seen one case, at least, of true bony ankylosis.

Many or few joints may become inflamed, but when one of the nerves of the upper extremity, which supply the hand, is the seat of the injury, many of the finger-joints are commonly affected.

Clinically, as well as pathologically, these cases resemble closely acute or sub-acute rheumatism on a limited scale. The diseased joints become slightly swollen, extremely tender to the touch, and painful on movement. Gradually, the more acute symptoms pass off, and, in the larger number of cases, a more or less complete ankylosis remains. This ankylosis is, as a rule, incomplete, and over a limited area movement is fairly free. The extent to which a limb may be crippled by this form of arthritis can scarcely be exaggerated, and, occurring as it does in combination with

other trophic lesions, it is liable to be accompanied by an amount of deformity and suffering not easily exceeded.

Alteration in Temperature.—The immediate result of division of any of the main nerve-trunks of the extremities is vaso-motor paralysis, and consequent hyperæmia of the paralysed area. As a result of this increased blood-supply, the temperature is raised above that of the corresponding part on the opposite side. The increase in temperature varies in different cases, but is usually about two or three degrees. After a few days, the alteration in temperature is less marked, and in the course of a few weeks the temperature not only sinks to the former level, but the paralysed area becomes several degrees colder than is normal. The fall may amount to eight or ten degrees.

The changes that have just been described as following on nerve-section, may also be met with as the result of any other injury to a nerve. It is quite a mistake to suppose that the various trophic changes are dependent upon some irritated or inflamed state of the nerve-trunk, for they are met with after simple section in cases where the nerve is completely divided, and in no way implicated in scar-tissue. In addition, it must be remembered that, within a few days of section, the degenerate nerve-tubes are quite incapable of conveying any nervous currents, and cannot therefore be the means through which the nutrition of the tissues may be actively influenced.

Diagnosis of Nerve-section.—The diagnosis of division of a peripheral nerve is usually an easy matter. In recent wounds, however, unless the surgeon bears in mind the possibility of such an injury, he is not at all unlikely to overlook it, the paralysis and loss of sensation being frequently unnoticed or uncomplained of by the patient. Later on, the muscular wasting and shortening, the 'reaction of degeneration,' evidenced by the use of the galvanic current, the paralysis, trophic changes, and loss of sensation make the diagnosis sufficiently clear. It must be borne in mind that, from a diagnostic point of view, the evidence adduced from an examination of the muscles is of much greater weight than that derived from an examination of the sense of touch, which, as has already been mentioned, may be to a great extent preserved.

TREATMENT OF DIVIDED NERVES.—In all recent cases of division of nerve-trunks, primary suture of the divided ends should

be performed. The nerves are very elastic, and on section retract to considerable distances, frequently necessitating an enlargement of the wound. If the cut ends are at all jagged or torn, fresh sections should be made, and contact ensured by thorough stretching. From three to six sutures are generally requisite, and are best passed by means of a small curved needle carried in the long axis of the nerve-fibres. It is quite immaterial whether the needle be passed through the whole thickness of the nerve-trunk or only through the sheath, so long as thorough apposition is obtained. There is no reason for believing that passage of a needle through the nerve inflicts any serious harm.

The best material for sutures is fine kangaroo-tendon. The writer's preference for this material is based upon the fact that he has seen cases in which suture with carbolised catgut failed, apparently because the sutures did not last a sufficient length of time. It must be remembered that nerves do not unite rapidly; if, therefore, there be any tension on the part, it is certainly advisable to use some material which will maintain the divided ends in apposition for a longer time than does catgut. Every endeavour should be made to obtain primary union of the wound, for, if much suppuration occur, separation of the recently united nerve by inflammatory products, or matting in fibrous tissue, is likely to ensue.

Supposing the divided nerve to have escaped primary suture, and the patient is not seen for some months later, an operation for resection of the separated extremities and secondary suture should be undertaken. There are not at present a sufficient number of recorded cases to allow of any opinion being offered, as to the amount of time that may elapse after which suture can be successfully performed. The operation should, therefore, not be withheld, in any case, simply on account of the length of time that has elapsed since the original injury. The application of an Esmarch's bandage materially facilitates the search for the nerve, but, at the best, the operation is liable to be prolonged. The incision should be made in the long axis of the nerve at the seat of injury.

It is often advisable to expose the nerve-trunk above or below, and then to trace it down until the cut end is reached. The divided ends are always adherent to the surrounding tissues, the upper being bulbous, the lower often atrophied. They should be freely separated and fresh sec-

tions out as cleanly as possible. There is no object in cutting away much of the lower end, for it is all equally atrophied. Neither need the entire bulb be removed—though the greater part of it should be—for it offers a better hold for the sutures than does the nerve-trunk itself. If the nerve seems much shortened, the ends should be thoroughly stretched before being sutured, and the limb should be put up in such a position as to ensure as little longitudinal tension as possible. The sutures should be of the same material and may be passed in the same way, as has been described in the account of primary suture.

The *prognosis* of cases in which nerve-suture has been performed must be somewhat uncertain. When the patient is young, when good apposition has been obtained, and when the wound has healed by first intention, it is most probable that the functions of the nerve will be restored, either completely or else in part. In some cases sensation may return and motion may never be regained; in other cases the reverse holds good.

The *length of time* required for this restoration is most various. In recent cases primary union of the divided ends is but rarely attained, and the process of degeneration and subsequent regeneration is necessarily a lengthened one. In cases of secondary suture, sensation sometimes commences to return within twenty-four hours, but a much longer time is requisite for the restoration of the atrophied muscles. In many cases, the surgeon must not be disappointed if no improvement makes itself apparent for weeks or months. The writer has seen patients, in whom restoration of function did not commence until nearly two years after suture. But, whilst waiting for repair, other treatment should by no means be neglected; it is most important to prevent, as much as possible, the deformities and trophic lesions which are almost certain to ensue. Perhaps the most important rule to observe is that the whole extremity which is the seat of injury, and especially the paralysed part, should be kept warm; cold is certainly prejudicial, and repair in many cases is apparently more rapid during the summer than the winter months. Galvanism is often useful, even in cases where muscular irritability is absent, and appears to have some influence in maintaining the nutrition of the part. It should be persevered with so long as any hope of union remains. Daily friction and shampooing of the limb should be practised, and any tendency to fixation of joints and muscular contrac-

tion should at once be combated. The treatment of cases of arthritis is most unsatisfactory at best. In the early stages, blisters are sometimes useful, and, as early as the inflammation allows, the patient should be anæsthetised and all recent adhesions be broken down.

PARTIAL SECTION.—Contrary to the opinions of some authors, the writer is quite convinced that partial section of a nerve-trunk is by no means so severe a lesion as complete division. It has been stated that trophic lesions of various kinds are more frequent after partial than after complete division. The writer has observed several such cases during considerable periods of time, and feels certain that the amount of paralysis, of anæsthesia, and of trophic lesions is in direct proportion to the amount of nerve-fibres divided. The prognosis of union in such cases is also better than in those of complete division, for the divided tubules are but little separated, and so can more readily rejoin.

In recent cases of partial division it is as well to suture the divided strands, more especially in cases where almost the whole trunk has been severed. If, however, the patient is not seen until the wound is healed, the treatment to be adopted will depend on the amount of function that is lost. Supposing this to be very considerable, it is advisable to cut down on the nerve at the seat of injury, then to resect the ends and perform secondary suture, if division be found to be practically complete. It is always best to do this if the functions of the injured nerve are almost lost, for it must be remembered that those which remain may be really dependent upon some abnormal distribution of another nerve-trunk, complete division of the damaged nerve having really occurred. Where an examination tends to show that but few nerve-fibres have been divided, the case may fairly be left alone so far as operation is concerned.

INJURIES TO PERIPHERAL NERVES.—Considering the almost innumerable injuries of peripheral nerves, it must be allowed that severe symptoms resulting from such an accident are relatively uncommon. It is probable that when symptoms do arise, they are due to implication of the nerve in the scar-tissue and to secondary neuritis, and not directly to the nerve-wound; and it is because a partially divided nerve can less readily contract, and so escape inclusion in the scar, that partial division of a filament is more likely to be followed by troublesome symptoms than if the division has been complete. The symptoms of injury to or irrita-

tion of a peripheral filament are—reflex contraction of neighbouring muscles, producing painful spasm, rigidity, and uselessness of the injured extremity; pain of a neuralgic nature radiating over an area of varying dimensions; occasionally, paralysis of neighbouring muscles. In hysterical patients the health may be seriously affected.

The *treatment* of such cases consists in removing the cause. If the wound has cicatrised, it will frequently be found that at one spot the cicatrix is extremely sensitive, and that any pressure exercised in this situation at once causes radiating neuralgic pains, and perhaps muscular spasm. If this be the case, the cicatrix should be completely excised. If any suspicion exist that the pressure of some foreign body, such as a shot, is the exciting cause of the symptoms, a careful examination of the supposed seat of irritation should be made, and any foreign body should be removed.

PRESSURE ON NERVES.—Pressure may be applied by external objects, or may be due to the growth of tumours, displaced bones in cases of dislocation, the callus thrown out in repair of fractures, implication in cicatrices, &c. The effects of pressure on a mixed nerve are most apparent in respect to its motor function; paralysis of muscle may be present, while sensation is retained; the reverse is rare. Cases of crutch palsy afford good examples of the effects of extraneous pressure, whilst paralysis from pressure on the nerves of the arm during sleep—especially drunken sleep—is also of common occurrence.

The *diagnosis* of such cases is usually easy, and the *prognosis* is good. *Treatment* by galvanism and friction, with abstinence from the use of the crutches, if these are the cause, usually results in a cure within a few days or weeks. Pressure on nerve-trunks by cicatrices is generally characterised by the gradual onset of the symptoms which are common to all cases of nerve-injury. Thus, the anæsthesia is preceded by numbing and tingling pains, and by parasthesiæ of various kinds. Paralysis and wasting of muscle are also gradual. Trophic lesions are slowly established. Such symptoms as those accompanying the gradual contraction of a cicatrix are a sufficiently clear evidence of pressure on a nerve. Supposing the anæsthesia and paralysis to continue, after a sufficient length of time has elapsed to allow of the cicatrix becoming more supple and less adherent, an operation should be undertaken in order to free the compressed nerve from the fibrous mass in which it is embedded.

INJURIES OF NERVES IN FRACTURES.—LACERATIONS OF NERVES.—Were it not for the extreme elasticity and toughness of the nerve-trunks, there is no doubt they would suffer in cases of fracture much more frequently than is actually the case. They do not, however, always escape. There are two ways in which nerves may be damaged in cases of fracture. They may either be torn at the time of the accident, or they may be compressed by callus. If torn at the time of the accident, the symptoms will, of course, supervene immediately, whereas, if gradually implicated in callus, the onset will be gradual, in the manner already described as occurring in cases of pressure on nerves by cicatrices.

Where a definite history of sudden, or else of gradual loss of function can be obtained, the diagnosis is rendered comparatively easy. This, however, is by no means always the case. The pain of the injury, the subsequent bandaging and splinting of the damaged limb, frequently prevent the patient having any very clear idea of the condition of his sense of touch and of his muscular power. It is often not until the splints are removed that paralysis or numbness is noticed. But even when the surgeon feels satisfied that a nerve is torn at the time of fracture, it is in all cases advisable to wait until union of the broken bone has occurred. Secondary suture of the lacerated trunk offers prospects of union which are practically as good as those of primary suture; and it is not worth while to make a simple fracture into a compound one, in order to unite a torn nerve.

The *treatment* of the injured nerve after union of the fracture has occurred is, however, clear. If there be any doubt as to whether it is a case of nerve-laceration, or one of callus-implication, it is as well to wait and see if improvement results as the callus is absorbed. If no such improvement occurs, an exploratory operation should be undertaken, the nerve should be exposed, and, if torn, should be sutured. If, however, there is no laceration of the nerve, but it is implicated in callus, the bone which surrounds it should be chiselled away. In some instances true pressure may be exercised, not by callus, but by fragments of comminuted bone. The writer has seen one such case, in which removal of an outlying portion of bone which compressed the median nerve and caused paralysis, was followed by rapid disappearance of all symptoms.

NERVE-INJURIES IN DISLOCATIONS.—As in fractures, so in dislocations, nerves

may be torn at the time of accident, or else simply compressed by the displaced bone. They may also be torn in attempts at reduction. It is in connection with dislocations of the shoulder-joint that such troubles are most likely to occur, and not only may the nerves forming the brachial plexus be torn in the axilla, but the whole of the cords of the plexus may be torn out from their attachments to the spinal cord.

The *treatment* of such cases is often most unsatisfactory. Where the dislocation is unreduced, and the symptoms are due to the pressure of the displaced bone, much improvement generally follows on reduction; but where the nerve-trunks have been torn, the case is little likely to improve, and though an operation for suture may be undertaken, the difficulties attending it are generally very great.

CONTUSIONS OF NERVES.—A severe blow on a nerve-trunk may be followed by all the symptoms which ensue on complete section; in other cases sensation may be lost while motion is retained; or the reverse may occur. The nerve itself may be either simply contused, and to the naked eye may present no abnormal appearance, or else it may be entirely crushed. The *prognosis* in these cases is necessarily most uncertain. It is not possible to ascertain accurately the condition of the nerve. In many instances rapid restoration of function ensues. In others, improvement is so slow that two or three years may elapse before the functions are entirely restored; and, in yet others, no repair ensues. The *treatment* is practically the same as that already recommended in cases of nerve-section.

PUNCTURED WOUNDS OF NERVES.—Punctured wounds of nerves are sometimes followed by symptoms indicating division of some fibres and irritation of others. Thus, partial anæsthesia and paralysis, with muscular wasting, may be combined with hyperæsthesia, and neuralgic pains with muscular spasm. In the early stage, the treatment consists of rest in order to allay the irritability of the damaged fibres, which are only in part divided, and are liable to be implicated in any inflammation that results from the injury. In the later stages, when the irritability has passed off, the treatment already recommended in cases of nerve-section should be adopted.

NEURITIS.—Neuritis may supervene upon any injury to a nerve, but it is fortunately of rare occurrence. There is no doubt that the cut ends of all divided nerves are most usually implicated in the inflammatory process by which the wound is healed;

but such inflammation is strictly limited to the injured portions, and causes no definite symptoms. The form of neuritis which is here alluded to tends to spread along the whole length of the nerve. It may be either acute or chronic. The changes common to all inflammatory processes are combined with gradual destruction of the nerve-fibres and swelling of the whole trunk.

The *symptoms* are intense pain both in the course of the inflamed nerve and also in its peripheral distribution, combined with muscular spasm, atrophy and trophic lesions. *Treatment* consists in rest, cooling applications, and leeching. In chronic neuritis, counter-irritation is most efficacious, and in obstinate cases nerve-stretching should be resorted to.

ANTHONY A. BOWLBY.

NETTLE-RASH. See URTICARIA.

NEURALGIA.—Neuralgia may be shortly defined as local pain without local signs of inflammation or disease.

Causes.—The causes are predisposing and exciting, but in very many cases of neuralgia no definite cause can be assigned. With regard to the first, an hereditary tendency to nervous affections—e.g. epilepsy or lunacy—is the most important. Any debilitating influences, whether mental or physical, predispose to neuralgia. The chief exciting causes are: 1. Exposure to cold. 2. Pressure or irritation of nerve-trunks. 3. Peripheral irritation. 4. Irritation or disease of the central nervous system.

1. Exposure to cold appears to act by setting up inflammatory changes around the nerve, but the exact manner in which the nerve is affected is not certainly understood.

2. Nerve-trunks may be compressed or irritated either by pressure on them, or implication of their substance by a tumour, or else by surrounding inflammation—e.g. the neuralgic pains caused by pressure of a thoracic aneurism upon the intercostal nerves is sometimes very severe. The pain is referred to the periphery of the affected nerve. The implication of nerves in the scars of cicatrising wounds affords an excellent example of pressure by inflammatory exudation. In stumps, neuromata are commonly found (see NEUROMA), and are the source of very severe neuralgic pains. Sometimes, slight wounds of the digits or other parts are followed by extremely tender cicatrices, pressure on which at one particular spot causes intense shooting pain, due to inclusion of a small nerve-filament at this point.

3. Peripheral irritation may reflexly cause neuralgic pains in very distant parts; surgically speaking, this is one of the most important causes of neuralgia. The following may be adduced as instances of this reflex neuralgia. A stone in the kidney may cause severe neuralgia of the testis; a carious tooth may cause facial neuralgia in any of the branches of the fifth nerve; a wound in the hand may cause pain in the arm or neck; a foreign body, such as a shot, pressing on a peripheral nerve may cause neuralgic pains, which are referred to all parts of the affected limb.

4. The irritation of a tumour pressing on the brain or spinal cord may cause neuralgic pains in distant parts. Pressure on the cord or nerve-roots, in spinal caries, often results in severe pains in the chest and abdomen. Structural disease of either the brain or cord may produce similar symptoms.

Symptoms.—The one essential symptom is pain. This pain is localised more or less accurately to the area supplied by a certain nerve or nerves. It is usually described as of a darting, shooting, or plunging character, and radiates from a central point. Pressure, upon the spot where the affected nerve emerges from beneath the deep fascia or from a bony canal, intensifies the pain.

Epileptiform neuralgia is the name given to a very severe and fortunately rare form of this disease, which from its obstinacy is very liable to come under the notice of the surgeon. This most painful affection (which is well described by Trousseau in his *Clinical Medicine*) almost invariably attacks the face, and may follow the course of any one or of all of the branches of the fifth pair of nerves. There are two varieties. In the one the pain is accompanied by spasm and twitching of the facial muscles; in the other there is no such spasm. The pain is not constant but paroxysmal, and is liable to much variation. As in other forms of neuralgia, many weeks or months may elapse between the attacks, which, when they supervene, are liable to be repeated day after day for a considerable time. The patients vary in age, sex, and constitution. They may be old or young, men or women, robust or weakly.

The paroxysms of pain are usually of a most startling character, and their onset is very sudden. Their duration varies from four or five seconds to half a minute, seldom exceeding the latter limit. They may be repeated so rapidly that the intervals are scarcely appreciable, or a considerable time may elapse between the paroxysms. The paroxysm may be started

by various causes, most of which act on the peripheral distribution of the fifth nerve. Quite suddenly, without a moment's warning, a draught of cold air, an attempt to swallow liquid or to masticate food, the slightest touch of the hair of the face or of the skin, an attempt at speaking, or a sudden noise may be followed by a severe pain. This, commencing at a single spot, rapidly radiates over the whole of the branch of the nerve which supplies the surrounding area, and spreads in many cases to the remainder of the face. At the onset of the paroxysm the patient frequently appears to lose all self-control. He grasps his head with both hands as though he would crush it, he clenches his teeth, clutches violently at surrounding objects, or writhes in agony on the floor. It is impossible to exaggerate the sufferings of these patients.

The precise character of the pain varies at different times and in different patients. To some it is 'like a bundle of red-hot wires being driven into the face and then twisted in all directions' (Walsham), to others of a stabbing and cutting character. Some patients describe the pain as similar to that experienced by severe crushing of a part, others say it is 'as if the flesh was being torn away.' The mucous membrane of the lips, gums, and nasal cavities is just as much the seat of pain as is the skin, and in some instances the secretions are variously altered, the nostril becoming hot and dry, or the eye becoming full of tears.

On account of the frequency with which movements of the mouth cause an attack, the patient often presents an appearance of extreme caution in his actions. When speaking, he does so with clenched teeth, and with lips scarcely parted. In eating and drinking his movements are very slow. His face is kept wrapped up to prevent the contact of any foreign body or of a sudden blast of cold air. Sometimes, under the perpetual mental strain, the patient's health gives way, for he is often almost incapacitated for sleeping or eating and drinking, and his whole thoughts are concentrated on himself. In other instances the health is maintained in a manner which is very surprising, and the general appearance of the patient, when free from pain, is often most deceptive. Occasionally, the subjects of epileptiform neuralgia seek relief from their sufferings in suicide, a termination which sufficiently emphasises the severity of the complaint.

Diagnosis.—The diagnosis of neuralgia is not difficult, but care is necessary not to

confound the pain caused by real and serious disease with a pain that is purely functional.

Treatment.—Apart from medicinal treatment, which will not be considered in the present article, the first essential is to discover and remove the cause. Thus, research should be made for any tumour or inflammatory growth forming on a nerve-trunk, for any source of peripheral irritation, and for disease of the central nervous system. Neuralgia of the fifth nerve has been completely cured by removing small fibrous growths on the gums, and by gouging away the alveolar borders of the jaw-bones, where these have been found to be unduly sensitive to pressure. In many cases, counter-irritation by means of blistering fluids, iodine, &c., produces excellent results; and in cases of neuralgia of the extremities a thorough course of 'massage' and shampooing is often most beneficial. In cases of sciatica and other neuralgic pains of the limbs, galvanism sometimes gives great relief. It should be applied for a space of ten or fifteen minutes daily, and must be persevered in for several weeks before a cure can be expected. The current need not be a very powerful one.

In addition to the removal, if possible, of the exciting cause, the operations of NEUROTOMY, NEURECTOMY, and NERVE-STRETCHING may be advantageously employed. The chief objection to the two former is that, except in the case of purely sensory nerves, the resulting paralysis from division of motor as well as sensory branches is a most serious evil, and every other method should be thoroughly tried before such an operation is undertaken on one of the nerve-trunks of the extremities. In cases of neuralgia in any part of the body, but especially in the case of such a disease affecting the branches of the fifth nerve, neurotomy almost always gives temporary relief. In some cases the relief is permanent, but in many more it is only temporary. The return of pain in any given area must not be interpreted as implying a reunion of the divided nerve, for this comparatively rarely occurs. Neuralgia is often reflex, being excited by any peripheral irritation; and where the original source of irritation has been removed, the nerve-centres may yet remain in a state of undue irritability, and may be excited by irritation of any other centripetal branch. In spite of such obstacles, the operation of neurotomy is fully justifiable in cases of obstinate neuralgia.

If neurotomy fails, the operation of neurectomy may be undertaken. The

rationale of such a proceeding is that after excision of a portion of the nerve-trunk reunion is less likely to occur. This is certainly true, but in most cases the return of pain is not due to such repair. It is the opinion of the writer that such an operation excels neurotomy only in those cases in which the excision of a portion of the nerve involves the division of other sensory branches—e.g. in excision of the infra-orbital the branches to the teeth and palate are also cut away. In all cases of neuralgia severe and obstinate enough to call for operative interference, nerve-stretching should always be practised before either neurotomy or neurectomy, for it is often equally or even more efficacious, and in the case of the motor nerves the damage done to peripheral parts is infinitely less. Further, in those cases in which neurotomy or neurectomy are performed, it is certainly advisable to combine nerve-stretching with such a procedure, the nerve being stretched before it is cut. The operation is one of universal application in all cases of neuralgia.

The treatment of epileptiform neuralgia is most unsatisfactory and uncertain, yet good and permanent results do follow surgical interference in a certain number of cases. As in other forms of neuralgia, nerve-stretching of either the inferior dental, the supra- or infra-orbital should be tried before division of these trunks, but either neurotomy or neurectomy, or excision of Meckel's ganglion, may be practised. Each operation is generally followed by some period of relief; the pain may not return for months, and it must be borne in mind that many patients are quite willing to purchase temporary immunity at almost any cost. They will submit to operation after operation, so long as the faintest hope of benefit remains.

ANTHONY A. BOWLBY.

NEUROMA.—A neuroma is a tumour of a nerve, but the structure of neuromas varies. They may be divided into (a) true, (β) false. (a) A true neuroma is one which is composed of nervous tissue. This tissue may either consist of nerve-fibres, medullated or non-medullated, or else of true ganglionic cells with a surrounding network of fibres. In almost all true neuromas the nerve-tubules are not continuous with those of the nerve-trunk to which they are attached, and, as a rule, are not arranged in any definite order, but form an irregular network mixed with a varying amount of loose connective tissue. The majority of the fibres are smaller than those composing

a normal nerve, and often, some of them have scarcely any medullary sheath. Although the matrix in which these fibres lie is generally composed of connective tissue, it may consist of myxomatous or sarcomatous elements. Neuromas composed of nerve-fibres or of ganglionic elements are very rare; the writer has not seen such a case.

(β) A false neuroma is a tumour situated on a nerve, and not itself containing any nerve-elements. There are several varieties of false neuromas, but the most common of such tumours are fibromas. These consist almost entirely of white fibrous tissue with but few connective tissue cells. Myxomas, gliomas, and sarcomas are also met with in nerves, the latter more commonly than the former. They differ from the fibromas in the greater rapidity of their growth, in their tendency to infiltrate rather than simply to push aside the nerve-tubules among which they grow, in their greater softness and succulence, and in their cut section being pink, homogeneous, and gelatinous, instead of white, shining, and fibrous.

Neuromas, either true or false, are most common on the nerve-trunks of the extremities; they vary in size from a pin's head to an egg, but are most commonly about as big as a nut. In shape they are usually rounded or oval, smooth on the surface and firm to the touch. Neuromas, especially those composed of fibrous tissue, frequently lie between the nerve-bundles, pressing them aside and not actually involving them in their growth. But, in other cases, one or more of the nerve-bundles may pass completely through the tumours.

Another variety of neuroma is the traumatic neuroma, which is met with in stumps after amputation, or in any nerve that has been completely or partially divided. Such tumours vary in size according to that of the nerve on which they are situated; they are, roughly speaking, about twice the diameter of their nerve-trunk, and their length is about double their width. They are smooth and oval, tapering at their extremities, and directly continuous with their nerve-trunk. They are generally adherent to the surrounding tissues, and, on section, may be seen, with the naked eye, to be composed of longitudinal bundles lying in a fibrous matrix. Under the microscope, they are found to consist of a mixture of fibrous tissue and nerve-tubules. The latter are smaller in diameter than normal nerve-fibres, and appear to be either old fibres which have atrophied from pressure, or else young tubules which are not fully developed.

In some cases the nerve-trunk above the neuroma is thickened and indurated to a variable length.

The 'painful subcutaneous tubercles' which are met with in the subcutaneous tissues—chiefly of the extremities—are included by some authors amongst the neuromata. The writer has examined many such tumours, but has never been able to demonstrate any connection with a nerve-filament. They are composed of fibrous tissue, and are most commonly found in women.

The *diagnosis* of neuroma depends partly on the symptoms induced by their presence, and partly on the physical characters they present when examined. The attention of the patient is first called to the tumour by pain, which varies in its character. It is felt both at the seat of growth and in the parts to which the affected nerve is distributed. It is often continuous, but is liable to sudden exacerbations. It is sometimes of a dull, aching, numbing character, but more often sharp, shooting, and of a neuralgic nature. As in true neuralgia, so in neuroma, the pain often radiates beyond the affected trunk, so that other neuromas may be suspected where none are really present. In addition to pain, the pressure on the nerve-trunk gives rise to various paræsthesiæ, and the patient complains of numbness, 'pins and needles,' tingling, and formication in the parts to which the nerve is distributed. Where the sensory nerve-fibres are completely compressed or crushed by the growth, absolute anæsthesia will ensue. This is rare. Muscular movements of a twitching character, and, occasionally, choreic or epileptiform convulsions result from irritation of motor fibres, whilst the complete compression of the same is indicated by paralysis of the muscles supplied by them.

The interference with the trophic nerve-fibres by the growth in rare instances results in the production of various so-called trophic changes. The chief of these are a smooth, glossy appearance of the skin, striation and brittleness of the nails, ulceration of peripheral parts, painless whitlows, loss of hair, increase or diminution of sweat, and wasting and loss of faradic contractility of the muscles.

On clinical examination by the surgeon, a neuroma will be found as a smooth, oval or rounded swelling, varying in size as before mentioned, and situated in the course of a nerve-trunk. It can readily be moved in a lateral direction, but is found to be scarcely, if at all, movable in the long axis

of the nerve on which it is placed. Pressure upon the tumour causes pain, both at the seat of the swelling and also in the parts applied by the diseased nerve; the latter point is important. The pain caused by the presence of the neuroma may be allayed by pressure exercised upon the nerve-trunk, between it and the spinal cord. The diagnosis of neuroma having been made, an opinion as to its intimate structure must depend chiefly upon the rapidity of its growth; in proportion as this is rapid, the probability of the sarcomatous nature of the tumour is increased.

Finally, it may be mentioned that neuromas, both innocent and malignant, may be multiple, being found in some instances on almost all the nerve-trunks of the extremities.

Treatment.—There is but one effectual treatment for neuromas, and that is removal by the knife. The incision should be made in the long axis of the affected nerve, and the tumour carefully enucleated with as little injury to the adjacent nerve-bundle as possible, for it should be remembered that, in many cases, the neuroma may be removed without dividing the nerve-trunk. In all cases in which excision of a portion of the diseased nerve becomes necessary, this should first be forcibly stretched to a sufficient extent to allow of immediate suture of the cut ends. For, if the nerve has been resected without this precaution being taken, it may be difficult or impossible to bring the cut surfaces into apposition. In cases where so large a portion of nerve has been excised as to render suture impossible, the chances of union are rendered much more uncertain, though no case must be regarded as hopeless in this respect.

ANTHONY A. BOWLBY.

NEUROTIC FEVER.—This term, which can only be considered as quite provisional, is here employed to denote that kind of pyrexia which is sometimes seen in patients the subject of severe traumatic lesions of the central nervous system.

Etiology.—Pyrexia has been clinically observed to occur in a number of different injuries and diseases of the central nervous system; and, so varied is the list, that the nature of the lesion can have very little influence of itself, excepting by some peculiarity of the way in which it injures the brain or spinal cord, and, above all, in the frequency with which it attacks certain portions of the central nervous system. The etiology of neurotic pyrexia will therefore be the etiology of a number of

affections grafted on to certain predisposing conditions, which may now be very briefly alluded to.

Such predisposing conditions are race, age, and constitutional disposition. Race has been alluded to elsewhere (*see SURGICAL FEVER*), and the influence of age is very well known, the tendency of young children to exhibit the symptoms of fever, on comparatively slight provocation, being an every-day clinical observation. No apology is here made for using the expression 'disposition,' for, none other being to hand, that will serve as well as any to indicate that in some persons the heat-producing metabolic processes are much less under control than in others, and that consequently, such individuals are, like children, subject to easily produced changes of body temperature. This same condition may be artificially brought about, in otherwise normal individuals, by the prolonged action of severe illness and physical exhaustion.

Pathology.—Although of later years considerable attention has been drawn to this subject, the experimental evidence upon it is extremely incomplete. It will make the situation clearer, perhaps, if we state at once the theory which at present obtains acceptance, and which is based on the work done up to the present time. It being well established that the heat-production of the body is brought about by the metabolic activity of the parenchymatous tissues (especially the muscles, &c.), it follows as a necessary corollary that the rise of temperature will vary in amount—(1) according to the activity of the tissue-metabolism, and (2) according to the state of the vessels on the cooling surfaces of the body. The complication introduced into the question of pyrexia, by necessary consideration of the influence of the vasomotor system in causing loss of heat, may here be passed by, for, as a practical fact, its immediate action is only to diminish the general effect, since the heat-production is much greater than the loss by cooling. We are, therefore, brought to consider the circumstances which influence the activity of tissue-changes, or, in other words, regulate the amount of heat produced. The only one recognised until lately as being possible was movement—i.e. contraction of muscles, produced, of course, by changes induced in the contractile tissues by the action of the central nervous system. But in the large majority of cases of neurotic pyrexia there is no such active movement at all; in fact, there is usually profound and extensive paralysis. We are thus led

to believe that, in these cases, the tissues produce a relatively enormous amount of heat, because their metabolic processes are no longer controlled by the damaged nervous system. General and experimental considerations have further extended this idea, until it is now believed, by some, that there are supreme heat-controlling centres in the cortex of the mid-parietal region of the brain, from which impulses pass down to an important subordinate centre in the medulla oblongata, and thence to smaller centres in the spinal cord. Each of these is supposed to inhibit with greater or lesser effect the peripheral tissue-changes, which consequently become greatly exaggerated when the controlling or inhibitory influence is withdrawn by disease or injury.

Symptomatology.—It will be sufficient if the above pathological theory is illustrated by the commonest clinical conditions, under which neurotic fever is met with in practical surgery. The part played by the central nervous system in the instances of traumatic fever, urethral fever, &c., is alluded to under those headings, and under that of surgical fever. In all these instances the pyrexia has been found to run a fairly definite course. We are now, however, introduced to a series of cases which present no such constancy of temperature curve except at the end—namely, just before death, when the case terminates fatally, as will be subsequently explained. Such cases are concussion of the brain, compression and laceration of the brain, hæmorrhage into the brain, especially into the ventricles and into the pons, laceration of the spinal cord and, occasionally, compression of the same; injury of the cord usually producing pyrexia when the lesion is in the cervical enlargement. Other rarer conditions are—tumours of the central nervous system and so-called hysterical cases. It is obvious, at once, that the weak point in the pathological theory above referred to, and which seeks to explain those cases, is that it is put forward in the absence of knowledge concerning the pyrogenous influence of foreign substances, such as extravasated blood, &c., on the brain or on the dura mater, the sensitiveness of the latter to mechanical stimulation being excessive. We can only repeat that, when the injury occurs in the neighbourhood mentioned above as the theoretical seat of the heat-centres and their connecting fibres, pyrexia is more likely to be produced.

Course of the Pyrexia.—In a large number of cases, the first effect of the injury is to produce a subnormal depres-

sion of temperature from SHOCK. This is quickly followed by reaction, which is accompanied by pyrexia, termed the 'fever of reaction.' If the case terminates fatally in a few hours, the temperature commonly rises steadily but rapidly to 107°–109° F., or even higher (111°, Brodie), and often continues to rise for an hour or two after death. If, on the contrary, the case recovers without another bad symptom, the temperature simply rises to 101° to 102° F., or even less, and falls gradually, to normal within twenty-four hours of its commencing to rise. Not infrequently the case, though ultimately proving fatal, lasts for several days. Under these circumstances the temperature usually rises to a comparatively low degree—viz. to 100° to 102° F.—and remains at about that point until a few hours before death, when it rapidly shoots up to 107° to 109° F., &c., which hyperpyrexia is occasionally continued after death. As hinted above, the hyperpyrexia at the end of these cases is the most striking feature of the temperature curve, and is possibly connected with the customary failure of the central nervous centres before the general systemic processes. In cases of hysterical hyperpyrexia it seems likely that we have to do with functional derangement of the calorific centres, especially such as exist in the cerebral hemispheres.

Prognosis.—Always of the worst, if the temperature rapidly rises towards hyperpyrexia. Bad, if there is profound and prolonged preliminary shock. Good, if with moderate shock the temperature soon reaches a moderate height and as soon returns to normal.

Treatment.—Hopeless, if hyperpyrexia has set in, and the cause is not removed. The ice-pack will be found to reduce the temperature one or two degrees, but it only delays the end a very little time, and the rebound after its use is greater. In cases of simple and moderate 'fever of reaction,' the ice-cap to the head, or, if necessary, iced towels on the trunk, should be applied. The obvious line of treatment, where feasible, is to attempt the removal of the cause of the pyrexia. VICTOR HORSLEY.

NEUROTOMY and NEURECTOMY. By the term 'neurotomy' is implied division of a nerve, by 'neurectomy' excision of a portion of its length. In either case, the nerve is exposed by an incision in a line parallel to its course, dividing the various structures that lie between the nerve-trunk and the surface. As in the case of ligature of vessels, there are certain

'seats of election' for the exposure of the chief nerves, and it is at such places that the nerve-trunks can be exposed with the least amount of damage to the surrounding parts. These operations are much facilitated, in the case of the extremities, by a previous exsanguination of the limb by the use of an Esmarch's bandage; the operation being rendered bloodless, the nerve is more easily exposed and its condition more readily ascertained. After the nerve has been found, it will generally be advisable to remove the bandage before stretching (if this is necessary), for, if left on, it constricts all the tissues to such an extent, that no impression will be made by the operation upon that portion of the trunk which lies above the bandage.

The Supra-orbital Nerve.—The supra-orbital notch can always be readily felt. The nerve, after emerging from the orbit, passes directly upwards towards the scalp. It may be exposed by an incision carried through the skin, fascia, and occipito-frontalis muscle. In this case, as in that of the supra-trochlear, the usual rule of making the incision parallel to the course of the nerve may be departed from, and the skin may be incised in a line parallel with the eyebrow, the reason being that transverse scars on the forehead are less perceptible than are longitudinal ones.

The Supra-trochlear Nerve. — The pulley for the superior oblique muscle may usually be readily felt at the inner angle of the orbit; the supra-trochlear nerve emerges immediately above it, and may be reached by an incision similar to that required for exposure of the supra-orbital nerve.

The Infra-orbital Nerve. — The infra-orbital canal, from which the nerve emerges, is in a line drawn from the supra-orbital notch to the canine tooth of the same side. The nerve may be exposed by an incision in this direction; it will be found at a considerable depth from the surface. In exposing any of the above nerves there is often troublesome bleeding from their accompanying vessels, and the operation generally takes a longer time than might be anticipated.

Meckel's Ganglion.—This ganglion has been excised for the cure of epileptiform neuralgia. It is reached as follows:—A crucial incision is made in the cheek, with its centre opposite to the infra-orbital canal; bleeding having been checked, a portion of the anterior wall of the antrum is removed with a half-inch trephine. A stout bristle, a piece of quill, or a slender probe, is then

passed as a guide along the infra-orbital canal, and the floor of the latter is carefully cut away from below with bone-scissors, until the posterior wall of the antrum is reached. During this part of the operation, great care must be exercised in order to avoid injury to the infra-orbital nerve. The trephine is now applied to the posterior wall of the antrum, and the bone having been removed, the ganglion will be most easily found by carefully tracing the nerve until its connection with the ganglion is reached. The latter may then be cut away with a pair of curved blunt-pointed scissors. Should there be troublesome hæmorrhage after the posterior wall of the antrum has been removed, pressure with the finger or with a pad of lint should be applied; the hæmorrhage is best avoided by taking great care not to lacerate with the trephine the soft structures posterior to the antrum.

The Inferior Dental Nerve.—Numerous operations have been practised for the exposure of this nerve. The following is the best:—The mouth being opened as widely as possible with a gag, an incision is carried along the anterior border of the ramus of the lower jaw, extending from the last upper molar to the corresponding tooth in the inferior maxilla. The mucous membrane being divided, the finger can be inserted between the internal pterygoid muscle and the ramus of the jaw. The muscle being pushed aside, the sharp spike of bone at the orifice of the inferior dental canal will then be the best guide to the nerve, which may be caught up as it enters the foramen by the backward sweep of a sharply curved aneurism-needle. Care is requisite to avoid mistaking the internal lateral ligament of the jaw for the nerve.

The Facial Nerve will be best reached by an incision extending from the lower part of the lobule of the ear forwards on to the ramus of the jaw. It quickly breaks up into its constituent branches.

The Spinal-accessory Nerve emerges from the posterior border of the sterno-mastoid, at a point a little above the middle of a line drawn from the clavicle to the mastoid process. It may be readily exposed at this point by an incision dividing the skin, platysma, and the deep fascia. Care must be taken not to mistake the superficial cervical nerve for the spinal accessory—the former curves forward round the sterno-mastoid, the latter runs in an oblique direction towards the back of the neck.

The Brachial Plexus is most easily exposed by an incision similar to that em-

ployed for the ligature of the subclavian artery—i.e. along the outer half of the clavicle. Lower down, the same nerve-trunks may be exposed by an incision carried down the middle of the axilla. Here also the *circumflex nerve* is most readily reached.

The Median Nerve may be exposed in the arm by an incision on the inner side of the biceps muscle; the nerve crosses the brachial artery in an oblique direction from without inwards. In the upper and middle part of the forearm this nerve is deeply situated, but at the wrist may readily be laid bare by an incision on the inner side of the palmaris longus tendon.

The Ulnar Nerve may easily be felt behind the internal condyle of the humerus. It may be reached in this situation by a longitudinal incision dividing the skin and fascia. In the forearm the nerve is deeply placed, but at the wrist may be reached by an incision on the outer side of the tendon of the flexor carpi ulnaris.

The Musculo-spiral Nerve is readily exposed by a longitudinal incision on the outer side of the limb, at a point midway between the external condyle of the humerus and the insertion of the deltoid. After the skin has been divided, the nerve may be easily felt to roll under the finger on the outer surface of the humerus; it should be cleared by separating the triceps from the biceps and brachialis anticus.

The Radial Nerve is easily accessible at the place where it passes from under the tendon of the supinator radii longus to the back of the wrist; here, by an incision on the posterior border of this tendon three inches above the wrist-joint, the nerve may be found, after dividing the skin and fascia covering it.

The Great Sciatic Nerve.—To define the course of the great sciatic nerve, draw a line from a point between the great trochanter and the tuberosity of the ischium, and half an inch nearer the latter than the former, to the middle of the popliteal space. The nerve may be exposed in the upper part of its course by an incision immediately below the gluteal fold, the biceps muscle being drawn inwards. If the incision be made below the middle of the thigh, the nerve will be found on the inner side of the same muscle.

The Internal Popliteal Nerve will be found, immediately beneath the deep fascia, in the middle line of the popliteal space.

The External Popliteal Nerve may be readily felt close to the inner side of the biceps tendon, covered by the skin and fascia.

The Posterior Tibial Nerve accompanies the artery of the same name down the back of the leg, its course being marked by a line drawn from the middle of the popliteal space to the hollow behind the inner ankle. In the upper part of the leg it is best exposed by an incision similar to that usually employed for ligature of its accompanying artery. At the inner ankle it will be found about a quarter of an inch behind this vessel.

The Anterior Tibial Nerve lies behind a line drawn from the front of the head of the fibula to a point midway between the two malleoli. The operation for its exposure does not differ from that for ligature of the anterior tibial artery.

The Musculo-cutaneous Nerve is easily reached by an incision just below the middle of the leg, in a line drawn from the front of the head of the fibula to the posterior border of the external malleolus. It will here be found emerging from the muscles on the outer side of the leg.

ANTHONY A. BOWLBY.

NEVILLE'S SPLINT. — Another name for **ARNOLD'S SPLINT**.

NIGHT-BLINDNESS. See **NYCTALOPIA**; **AMBLYOPIA**.

NIGRITIES. See **CHLOASMA**.

NIPPLE and **AREOLA**, Diseases of the.—**MALFORMATIONS.**—These may be congenital or acquired.—*Congenital Absence of the Nipple (Athelia)* is only met with in absence of the mamma. *Multiple Nipples (Polythelia)* are very rare, except in conjunction with multiple breasts. *Acquired Malformations.*—Complete destruction of the nipple has been met with as the result of burn. *Flattened Nipples* are not uncommon either from an error in development or from the pressure of the dress. This condition is of no importance unless the patient becomes pregnant. It may then be necessary, shortly before labour is expected, to raise the nipple by the occasional application of a small cupping-glass or a breast-pump, or by the suction of a strong infant or an adult. The parts must be bathed with warm water and gently manipulated. Violent dragging on the nipple, to 'draw the nipple-strings,' must of course be forbidden.

Fissures of the Nipple. Sore, Cracked, or Excoriated Nipple.—These occur during lactation. The causes are the constant moisture of the part, want of cleanliness, or the biting of the child. Thrush or

aphthæ in the child's mouth are variously asserted to be the cause and the effect of the sore nipple.

Symptoms.—The nipple swells and often assumes the form of a mushroom. It is at first red and excoriated, but not actually ulcerated. There is a slight serous or semi-purulent discharge. In the more advanced stages fissures form, radiating from the nipple into the areola. Their edges are raised and indurated, the floor is dark red and bleeds readily. Prominent granulations may project above the edges. The ulceration may extend, and even cause destruction of the nipple. The pain is excessive, the act of suckling becoming almost unbearable.

Treatment.—Sore nipples may be prevented by scrupulous cleanliness. The nipple should be frequently sponged with a concentrated solution of boracic acid, which, being tasteless, will not cause the child to refuse the breast. Brandy and water is often used for the same purpose. If a sore nipple threatens, an india-rubber shield should be used when the child is sucking. If a fissure forms the child must not be applied to the breast, but the milk must be drawn with a breast-pump. The following applications will be found useful. In the early stages, oxide of zinc and starch-powder; in the later, carbolic acid lotion (1 in 20), painted on twice a day; solid nitrate of silver occasionally to the fissure; Liq. plumbi f3ss., Sp. rect. f3j., Aq. ad Oj., applied on lint; boracic acid ointment. In some cases painting with flexile collodion gives relief. If the condition be neglected, abscess in the areola or mammary abscess may follow.

Eczema of the Nipple.—The nipple and areola are occasionally the seat of true eczema. The parts become red and tender, small vesicles form and burst, leaving a raw surface, from which an abundant serous discharge flows, often drying into crusts. There is much itching and uneasiness. Both nipples may be affected. It is most common during suckling, but is also met with as a part of general eczema, and more rarely as a consequence of scabies. It is very difficult to cure. The following are amongst the most useful applications:—Nitrate of silver lotion (gr. ij. to f3j.), with the occasional use of a stronger solution (gr. xx. to f3j.); lead lotion; calamine lotion; glycerine of borax; carbonate of lead ointment; zinc ointment. The extra-pharmacopœial remedies of most service are boracic acid lotion (concentrated solution), boracic acid ointment, boro-glyceride, glycerole of the sub-acetate of lead, and glycerole of lead

and vaseline ointment. Extract of belladonna, in the proportion of ʒj. to ʒj., may be added to these ointments.

So-called 'Eczema of the Nipple' as a precursor of Cancer.—Sir James Paget has called attention to a condition of the nipple closely resembling eczema, which he has observed to be followed by cancer in the gland after lasting from one to three years. The areola is in some cases intensely red, raw, and finely granular, 'like the surface in very acute diffuse eczema'; there is a copious yellowish discharge, which dries into scabs. It is accompanied by itching and burning sensations. In other cases the disease is more like psoriasis, the surface being covered with dry scales. As a rule, the morbid condition does not extend beyond the limits of the areola; occasionally, superficial ulceration takes place, ending in complete destruction of the nipple. The base of the ulcer is indurated. When cancer follows it is usually directly under the nipple, but there may be an interval of apparently healthy tissue between. The pathology of the disease has been accurately investigated by Mr. H. T. Butlin. He finds the following conditions:—Proliferation of the mucous layer of the epithelium and small-cell infiltration of the corium of the areola; dilatation of the galactopherous ducts, with proliferation of the epithelium, sometimes choking the lumen; small-cell infiltration around the diseased ducts; proliferation of the epithelium in the acini, and finally the extension of the epithelium into the surrounding structures. No treatment is of any use. Sir J. Paget considers it advisable to anticipate the development of cancer by removal of the breast, when this so-called eczema is met with in women about the age at which cancer is likely to develop, and more especially if there is a strong hereditary tendency to the disease.

Chancre of the Nipple.—Primary sores are occasionally met with in wet-nurses from the infection of syphilitic children. The mother is never affected in this way. *Mucous Tubercles* are sometimes seen on the nipple in secondary syphilis.

Abscess of the Areola is not uncommon in nursing women, especially in cases of sore or fissured nipple. There are the usual symptoms of redness, swelling, heat, and pain, followed by the formation of a small fluctuating swelling. The pus may burrow subcutaneously, but shows no tendency to extend deeply into the mamma.

Treatment.—As soon as the redness and swelling appear, the child must be removed from the breast and the milk drawn

with a breast-pump. Extract of belladonna and glycerine (equal parts) may then be painted on and hot fomentations applied. If this fails to arrest the formation of pus, the abscess must be opened, as soon as fluctuation is recognised, by a small incision radiating from the nipple.

NODES. See PERIOSTITIS; SYPHILIS.

NOMA.—A term applied by old writers to Phagedæna of the Female Genital Organs, and also to Cancrum Oris. See CANCRUM ORIS.

NOSE, Diseases of the.—**CONGENITAL DEFORMITIES.**—The external parts of the nose may be entirely absent, an aperture alone being left, owing to suppression of the nasal process of the embryonic face, together with fusion of the eyes into one in Cyclopean fœtuses. Or the nostrils may exist as a couple of cartilaginous snouts without the support of nasal bones, orbital cleft and some defect of the eye usually coexisting.

The nose may be perfect on one side and malformed on the other, of which the writer has seen an instance. In a case seen by the writer, under the care of Mr. Chauncy Puzey, a male infant had a peculiarly broad, flattened, and grooved nose, owing to imperfect apposition of the nasal bones and septum, the effect of which was a deep median furrow, on the sides and floor of which the skin was stretched continuously, making manifest the character of the defect. Operative treatment has very much reduced the deformity.

OCCCLUSION of one or both nostrils may exist in front, while bony closure of the posterior nares may be found behind. As further instances of congenital deformity, a minor degree of one of the above deformities has been seen in the form of a fissure of the nostril and a narrowed fissure of the eyelids. The malformation in hare-lip, also, so far affects the nostril as to be worthy of incidental mention.

Treatment.—These defects are rare curiosities, but are sometimes susceptible of improvement by plastic operation, the plan of which in each instance will be devised by the ingenuity and common sense of the surgeon consulted.

ACQUIRED DEFORMITY.—Deformity of the nose may occur in after-life in consequence of injury or disease.

Total loss.—The nose may be cut off at a single blow, or may disappear, bones and soft parts, as the result of syphilitic necrosis and erosion. **Partial loss** may result from a less severe process of necrosis and ulceration in syphilis, or from the erosion of lupus.

Flattening of the nose may likewise result from the loss of the nasal bones by syphilitic necrosis, without affection of the external soft parts. A similar depression and flattening may follow bad fracture, without loss of the bony framework of the nose, which is here simply displaced.

Considerable lateral inclination of the nose, to even a grotesque extent, may result from fracture, or may exist without previous injury. A slight degree of deviation from the middle line is present in most people, and this is sometimes exaggerated in the case of long noses to the degree of caricature.

Treatment.—For total loss of the nose a reconstructive plastic operation may be undertaken, by dissecting an integumentary flap of suitable shape from the forehead (the Indian method) or from the upper limb of the patient. In the latter, the method of Tagliacotius, the arm is immovably attached to the head, where it has to be maintained during union of the flap. For partial reconstruction of an ala or other portion of the nose, a plastic operation on a smaller scale is effected by taking a flap from the cheek. Such procedures are only admissible after entire soundness of the tissues has followed the disappearance of all trace of ulceration and inflammation, and their results are not satisfactory. For their detailed execution, see the article on RHINOPLASTY. An artificial nose of enamelled silver, supported by a spectacle-frame, is probably more successful in restoring the natural appearance of the face. To prevent or correct the deformity that may result from fracture, see the next paragraph.

INJURIES OF THE NOSE.—**Fracture of the nose**, the result of blows or violent falls, is sometimes attended with much disfigurement, owing to ecchymosis and swelling of the integuments. Through this, however, the fracture of the nasal bones or septum may be recognised by mobility, crepitus, or alteration of shape.

The depressed or displaced state of the fractured bones is apt to be perpetuated as a deformity, owing to the rapidity with which union takes place. Depressed nasal bones should, therefore, be at once elevated under chloroform by strong forceps covered

ith wash-leather, by means of which also the septum can be straightened. A splint of collodion and lint may be made to support the bridge of the nose, and it may sometimes be necessary to plug one of the nostrils.

A plan of treatment, recommended by the writer, consists in waiting a day or two until the chief tenderness has gone, ointments or cold applications being employed in the meanwhile if apparently required, after which the systematic manipulation of the nose is frequently practised every day, beginning before the end of the first week. It does not matter how great the immediate deformity at the time of injury, so that the nose be not permitted eventually to acquire a bad shape. This daily manipulation will effect the ultimate acquisition of any shape that may be desired, even to the improvement of a nose which, before the injury, may have been ill-shaped. The greater part of this daily fingering can be done by the patient under the superintendence of the surgeon, who inspects from time to time, and makes suggestions as required.

Wounds of the nose, operative or accidental, should be closed by the neat application of sutures, when not attended by great loss of skin or excessive bruising of the cut edges. In the latter event the injury should be left to granulate, and be suitably dressed with an antiseptic ointment, supplemented by washing with warm antiseptic lotions.

Foreign bodies are introduced by children through the nostril for the amusement of passing them back and ejecting them by the mouth. Such objects as peas, beans, buttons, pencils, bits of rolled paper, cabbage-leaf, &c., serve for the experiment, which, whether self-inflicted or vicariously performed, now and then fails, and the object sticks.

The removal may be easy or difficult according to circumstances. In the event of much pain and tenderness, and restiveness on the part of the child, the difficulties may be great without an anæsthetic. For extraction forwards by the nostril, a pair of slender-beaked forceps, toothed at the end, will answer the purpose. In easy cases, ordinary dissecting-forceps may answer. Or the object may be pushed back and ejected by the mouth, care being, if possible, taken that it be not swallowed, or, what is worse, admitted into the glottis or trachea.

Blood-tumour of the septum may occur in association with fracture, and its spontaneous disappearance may usually be

looked for. *Acute abscess* of the septum may follow fracture or blood-tumour. The treatment is incision in one nostril, with excision of a fragment of cartilage, at the margin of the opening thus made, to further drainage. See SEPTUM NARIUM, Affections of the.

DISEASES OF THE SKIN OF THE NOSE.—Persons of bibulous habits, more especially men, sometimes become the subjects of what is called 'bottle nose,' in which the nose, with or without the adjacent portions of the face, is reddened, congested, and irregularly swollen. This appearance and convivial habits are often combined; but the same appearance may now and then be found in abstemious persons (see ACNE ROSACEA).

Lipoma nasi is a peculiar enlargement of the nose, greatly resembling in shape that of some true 'bottle noses.' This affection is nothing more than a chronic inflammatory hypertrophy of the nasal integument, and is remediable by operation. The thickened masses of skin are carefully dissected off the nasal cartilage, the latter being protected by a finger kept within the nose. The greater part of the excrescence should be removed, but it is not necessary to excise every fragment of thickened skin. The resulting sore granulates up under appropriate dressing, and the thickened fragments atrophy in the process of healing. No 'cosmetic' operation is better worth the undertaking.

Little warts, pimples, or congenital dermoid tumours (moles) may be situated on the nose, but are commonly not interfered with, though their removal would often improve the appearance of their possessor. The skin of the nose may also be the seat of adenoma—a rare affection, however, in this situation.

Epithelioma may occur at the tip and orifice of the nose in old persons. The writer has seen two cases, of which one was excised successfully with the cartilage of the organ. A deformity was left, but in some cases plastic reconstruction might be done. In the other case the feeble health of the patient did not permit operation, and the disease ran its course.

Rodent ulcer is more common than epithelioma, and although usually met with in old age and middle life, it sometimes occurs at an earlier period. It usually attacks the ala at first, when, from being a scabby excoriation, it becomes a small chronic ulcer, having a circular or irregular shape, with a slight induration round the margin. Excision well beyond the margin

and floor of the ulcer should be practised. See CARCINOMA; ULCERS.

Lupus is a chronic inflammatory affection of the skin, occurring, as far as the nose is concerned, in youth and early adult life, mostly in the female sex. The disease presents various distinctive appearances and effects.

The nasal integument covering the cartilage, chiefly at one of the alæ, becomes scabby superficially, and covered with granulations beneath. This may exist without loss of shape, the organ simply presenting the condition of a chronic sore. A severer degree consists in a gradual erosion of the tissues, including the cartilage, beneath the superficial coating of granulations, from which serum and pus exude, drying into scabs. The term '*lupus exedens*' is applied to the severest cases of deforming lupus.

The *diagnosis* is chiefly a question of age. All flabby ulcerations of the nasal skin, which do not heal spontaneously or speedily in young persons, are varieties of lupus, the recognition of which is rendered more certain if occurring in persons of an obviously strumous habit, though it often occurs without assignable cause or constitutional taint. Chronic ulcerations of inveterate character in the same situation in middle life, and not amenable to anti-syphilitic treatment, are almost sure to be rodent ulcer.

Treatment.—The early appearances of lupus, before erosion has become apparent, may be so mild and restricted as to mislead the observer into a reliance upon weak lotions and ointments, under the impression that healing is likely to be promoted. Even an occasional application of caustic substances, with temporary improvement, is apt, without perseverance, to dishearten or disgust both the patient and the practitioner. The tissues which are morbidly affected require to be removed, and this is best effected by scraping them away. A blunt knife, or a Volkmann's sharp spoon, will do this best. The same effect may be produced by rubbing the granulations into a pulp with chloride of zinc, or nitrate of silver, sulphate of copper, potassa fusa, &c.; by freely treating them with nitric acid, acid nitrate of mercury, and other strong liquids; or by burning them with the red-hot iron, Paquelin's thermo-cautery, and the like. All these methods, if thoroughly and repeatedly used, accomplish the same object, that of removing from the surface of tissues still healthy, the baneful influence of tissues hopelessly diseased and exerting a chronic contagious effect if left

behind. Any general constitutional management, such as the selection of a diet suited to the existing strength and digestion of the patient, and attention to essential comfort, may be required in lupus, as an incidental part of the treatment. See LUPUS.

DISCHARGES FROM THE NOSE.—Nothing is more common, at all ages, than the occurrence of a watery discharge on exposure to wet or dry cold. The effect may be quite transitory if the cause be not much prolonged. Some persons are extremely sensitive, and are affected with running at the nose on slight provocation of the above nature, and liable to severe and protracted catarrh if the cause of the preliminary running be maintained. The discharge then becomes thicker from secretion of mucus, which eventually may become purulent. Much inconvenience, a certain degree of illness, and generally frontal headache, attend severe nasal catarrh, which invades the frontal sinuses as well as other extensions of the nasal mucous membrane. The disease is believed to be frequently a constitutional infection as well as a local catarrh, and its simultaneous or consecutive appearance in persons living or associating together leads to severe '*coryza*' and '*influenza*' being regarded as somewhat '*infectious*.' Warmth and nursing are the utmost required for treatment, which is more generally omitted altogether, as most people in this climate are accustomed to perform their duties whether thus affected or not. Some believe they can cut short a cold at the very commencement by the prompt and frequent use of a snuff containing nitrate of bismuth and morphia in powder. In severe chronic catarrh, the use of the NASAL DOUCHE is most agreeable and also useful. It is preferable in the form of cold water, to which may be added a trace of common salt, chloride of zinc, borax, boracic acid, or chlorate of potash.

Chronic Coryza is a common symptom of inherited syphilis in childhood and infancy. An acid sero-purulent discharge fills the nostrils and reddens the skin at the orifice by irritative contact. The nasal douche is here invaluable. If this local washing be not speedily effectual, the internal administration of mercury (if it has not previously been otherwise necessary) must be resorted to. The most convenient mode is in the form of grey powder, one-third or half a grain at a time, once, twice, or thrice a day. See RETRO-NASAL CATARRH.

OZENA is the name given to a more intractable nasal discharge, muco-purulent

character, attended with much fetor, associated with syphilis, especially the inherited form, and almost always a sign of ulceration of mucous membrane and necrosis of bone in the nasal cavity. Depression of the nose and notched edges to the upper incisor teeth, when present, reveal at a glance the constitutional features of the local malady.

The nasal douche, with solution of chloride of zinc, one-eighth of a grain to the ounce, frequently and persistently used, is all-essential for treatment, and may be necessary, in the first instance, to remove the abominable smell, and otherwise facilitate the examination of the patient.

In adults suffering from tertiary syphilis, a similar condition will be found attending necrosis of the bones inside the nose, and multiple ulceration of that cavity and of the palate and mouth. Here also the nasal douche, medicated as above, is a source of daily comfort and satisfaction to the patient. But the internal administration of mercury, as grey powder, one grain at a time, given thrice, twice, or once a day, will suffice to promote sound healing, when supplemented by removal of loose pieces of necrosed bone.

NECROSIS OF THE BONES lining the nose most commonly occurs in syphilitic persons. In adult life it is usually the tertiary degree of acquired syphilis, while in children or adolescents it is the inherited form of the disease. At first, gummatus tumours form in the submucous tissue and periosteum, chiefly of the palate, and if the disease continue untreated, the gummy tumour or tumours burst, decomposition ensues, and progressive ulceration of the soft parts, with baring of the bone and its necrosis takes place. The disease is seldom confined to the nose or mouth, but is commonly shared by both cavities.

Fetor, purulent discharge, with a sense of exposed bone on using a probe or director passed into any aperture in the mucous membrane of the palate or nostrils, will reveal the condition of things, and enable the surgeon to feel whether the bone be loose enough for detachment.

Treatment.—Introduce a pair of dressing- or sequester-forceps and extract any pieces of loose bone that readily move, if the mucous apertures be wide enough for the purpose. This may frequently be done simply, speedily, and with no more pain than many patients are willing to bear. In the event of great tenderness, or any difficulty in at once extracting the bone, place the patient under an anæsthetic, and

enlarge such apertures as require it and seem most convenient for extraction. Be prepared, in the event of much bleeding (for it is sometimes very profuse), to employ vigorously the hot douche with a Higginson's syringe, by which means it can be quickly applied and the bleeding speedily stanchied. *See* ROUGE'S OPERATION.

For after-washing, chloride of zinc in tepid water, an eighth of a grain to the ounce, or a grain to the pint, may be used. If there be other gummata arising, or persistent ulceration of the soft parts, the use of washes and lotions will not be sufficient, however assiduously employed. But a grain of grey powder in the adult, and a third or half a grain in the young, given thrice, twice, or once a day, will procure eventual healing.

NURSING. *See* SICK-ROOM, Management of the.

NYCTALOPIA. — Night-blindness. Often, but incorrectly, used to denote *day-blindness* (Hemeralopia). *See* AMBLYOPIA.

NYSTAGMUS.—This name signifies an involuntary and more or less constant oscillation of the eyes. The movements are, in nearly all cases, bilateral, similar, and synchronous in the two eyes. They accompany, and do not impede or otherwise affect the normal voluntary movements. In different cases they vary much in direction, velocity, and amount, and, in the same case, they usually vary to some extent with the position of the eyes and head, and with the patient's state of mind, being increased by nervousness or excitement.

Causes and Pathology.—The oscillations of the eyes are, probably, the expression of abnormal action in the centres which preside over the ocular movements. In a large majority of cases, the affection occurs in association with some imperfection of vision dating either from birth or from very early infancy, such as congenital amblyopia without ophthalmoscopic changes, congenital defects in the discs, microphthalmos, high degrees of refractive error, albinism, congenital cataract, corneal opacities left by purulent ophthalmia in the first weeks of life, and so forth. In these cases, the disordered movements may reasonably be attributed to the absence of normal visual impressions, and the consequent want of stimulus to fixation, at the time of life when the centres for ocular movements are normally developed and trained. In the uncommon cases in which a congenital nystagmus goes with

normal or nearly normal vision, an independent defect in the development of these centres must be assumed. The affection sometimes shows a remarkable tendency to hereditary transmission; thus it was ascertained in one instance (Lloyd Owen, *Ophthalmic Review*, vol. i. p. 289) to have been present in nine individuals belonging to four generations, and to have been transmitted in such a manner that the male children of the female members of the family were the only ones affected, the females themselves being entirely exempt. Beyond a general prevalence of hypermetropia, no family ailment, nervous or otherwise, was discoverable; the nystagmus was present from birth, and persisted unaltered throughout life.

Nystagmus is met with as an acquired disease amongst *coal miners*, especially affecting those who have to work in a stooping, cramped position, or lying on the side. The cause of the affection, in these cases, is no doubt, to some extent, analogous to that already indicated. The miner works between black walls with a very feeble light; the stimulus to fixation is reduced to a minimum, while at the same time the necessity for constantly turning the eyes strongly upwards or to one side, in consequence of the position above referred to, makes an excessive demand upon the energy of the nerve-centres. Perverted action is the consequence. The effect of a stooping position, in increasing or inducing the oscillations of the eyes, is sometimes very evident on clinical examination in cases of miners' nystagmus. Lastly, nystagmus occurs, occasionally, as the result of injury to the head and in cases of disseminated sclerosis, in which conditions the disturbance in the brain-

centres must be assumed to be altogether independent of ocular conditions. The commonest form of nystagmus is that in which the excursions of the eyes are horizontal, the least common that in which they are purely vertical. Oblique movements and rotatory movements around the antero-posterior axis are not uncommon. In the congenital variety, the patient is not, as a rule, troubled by any appearance of oscillation in the objects at which he looks, while in the acquired forms it is often otherwise, and the dancing of objects before the eyes may render work impossible. Although the will has usually no direct influence in causing or arresting the movements, the patient often acquires the habit of keeping his head and eyes in the particular position in which the movements are smallest; in some cases they cease entirely during strong convergence. In a few cases the head also makes continuous oscillatory movements; whether these latter are ever of a compensatory nature is doubtful.

Treatment.—In all cases of congenital nystagmus, an examination should be made as to the cause of the amblyopia which underlies it. In some, an operation for cataract will be indicated; in others, the correction of high refractive errors; while, in the absence of both these faults, blue glasses will sometimes be found to increase the acuity of vision and lessen the nystagmus. In miners' nystagmus, a total discontinuance of underground work, together with iron and strychnia, has in many cases effected a cure, partial or complete; the removal from the mine is the essential step, and a return to it, at any future time, is likely to bring about a return of the nystagmus. PRIESTLEY SMITH.

O

OBTURATOR ARTERY.—This vessel normally arises from the anterior division of the internal iliac artery, runs along the side of the pelvis, passes through the groove at the upper part of the obturator foramen, and dividing into two, embraces the fleshy origin of the obturator externus muscle. In the proportion of 1 in 5 cases, however, the vessel arises from the deep epigastric, and drops down into the pelvis to reach the obturator foramen; in this course it is in relation with the upper

end of the crural canal—the crural ring. In about one-third of the number of cases met with, the artery passes in contact with the femoral vein, and hence to the outer side of the ring; in the remaining instances the artery encircles the ring. It is this latter position which renders the artery surgically important, as in it the vessel may be cut when an incision is made to relieve the constriction in femoral hernia. The former variety is called the safe, the latter the unsafe, abnormality of the vessel.

To prevent wounding the vessel, a blunt-pointed knife should be used to incise the constriction. If it should happen that the artery is wounded, one or other of the following methods may be adopted to stop the hemorrhage:—

(1) Compress the bleeding point for five minutes between the finger and thumb.

(2) If this is insufficient, enlarge the wound slightly and tie or twist the bleeding point or points.

(3) If neither avail, pass a threaded needle around the bleeding point and tie it.

(4) If no other means avail, make an incision as for ligature of the external iliac, and reach the bleeding point by pushing aside the peritoneum. JAMES CANTLIE.

OBTURATOR HERNIA.—The rupture escapes through the obturator canal. This canal is placed at the upper and outer part of the thyroid foramen, and is directed from behind forwards and inwards. The hernia pushes in front of it the fascia covering the obturator externus muscle, and perhaps, also, a few fibres of that muscle. It appears on the surface beneath the pectineus, with which muscle its fundus is covered. The tumour is above the adductor brevis, is behind and to the inner side of the femoral vessels, is to the outer side of the tendon of the adductor longus, and to the inner side of the capsule of the hip. The neck of the sac is in the obturator canal. It would appear that the obturator hernia is found with equal frequency to the inner and to the outer side of the neck of the sac. In about one-fifth of the reported cases it has been found behind it. The contents are usually small intestine, without some omentum. In one recorded instance a part of the bladder occupied the rupture. This form of hernia is, as a rule, met with in females of from forty to fifty years of age.

It is doubtful if the rupture, when of its ordinary size, can be diagnosed unless it be the seat of some acute change. The tumour is nearly always very small—so small that it causes but a very indistinct swelling beneath the pectineus muscle. Strangulation has frequently occurred in this hernia, and the rupture, when so circumstanced, has been reduced both by taxis and by herniotomy.

When the rupture is strangulated, there will be the usual symptoms of that condition, together with an absence of signs of strangulated hernia in any of the usual situations. Beneath the pectineus muscle there is a small, hard, tense tumour, which

is the seat of some pain, is tender and dull on percussion. There is pain on moving the hip, especially when it is moved actively. Pain may be complained of along the course of the obturator nerve. It is said that the neck of the sac has been felt and recognised through the vagina.

In applying the taxis, the thigh should be flexed, adducted, and rotated a little outwards. The pressure should be applied in a direction from before backwards, with a slight inclination outwards, so as to correspond with the line of the obturator canal.

In performing herniotomy, an incision from two to three inches in length is made over the tumour, parallel to the femoral vessels, and about one inch to their inner side. The fascia lata is exposed and divided, and the pectineus muscle is laid bare in the incision. The muscle is incised vertically in the line of the original incision, and the fundus of the sac will be exposed.

The stricture will be found at the neck of the sac in the obturator canal. The director must be introduced on the inferior aspect of the neck, and the stricture divided by cutting, either directly downwards, or downwards and a little outwards.

FREDERICK TREVES.

OBTURATORS. See CLEFT PALATE, The Mechanical Treatment of.

OCULAR MUSCLES, Affections of the.—The mechanism presiding over the movements of the eyes consists of three distinct parts: the muscles attached to the outer surface of the globe; the nerves, which convey impulses to the muscles; the brain-centres, in which the impulses originate. A clear conception of the way in which this complex mechanism acts must be gained, before the various symptoms which indicate disturbance of it can be understood. Within certain limits imposed by its attachments, each eye can be moved in all directions around an imaginary point situated about 2 mm. behind the centre of the globe. When the head is upright, and the eyes look straight forward at a distant object—i.e. when the visual axes are perpendicular to the plane of the face—the eyes are said to be in their primary position.

MUSCLES.—Reckoning from the primary position, the action of the individual muscles is as follows:—The internal rectus turns the eye directly inwards. The external rectus directly outwards. The superior rectus chiefly upwards, but at the same time a little inwards, causing a slight inclination of the vertical meridian of the cornea inwards

(towards the median line above). This twisting action depends on the fact that the optic foramen, from the margin of which the muscle takes origin, lies not directly behind the eyeball but a little nearer to the median line of the skull. The inferior rectus chiefly downwards, but also slightly inwards, with an inclination of the corneal meridian outwards, for the same reason as in the foregoing case. The two oblique muscles send their tendons, not from behind forwards like the recti, but rather from side to side; their chief action, therefore, is to twist the globe upon its antero-posterior axis; but as they do not lie parallel with the equator, but pass to their insertions somewhat from before backwards, they also move the eye in oblique directions intermediate between the horizontal and the vertical. Thus, the superior oblique turns the eye downwards and outwards, and inclines the vertical meridian of the cornea inwards; it acts together with the inferior rectus, and counteracts the twisting action of the latter. The inferior oblique turns the eye upwards and outwards, and inclines the vertical meridian of the cornea outwards; it acts together with the superior rectus, and counteracts the twisting action of the latter. When the eye stands in any position other than the primary, the actions of the individual muscles are somewhat modified, for the directions in which they pull are altered in relation to the chief axes of the eye. In simple upward, downward, and horizontal movements from the primary position, the vertical meridian of the cornea remains vertical, but in oblique movements it becomes slightly inclined in the direction of the movement; thus, when the eye is turned upwards and to the right, the meridian of the cornea is inclined slightly, its upper end being towards the right, and so on for other movements of like kind.

NERVES.—The ocular muscles are actuated by three pairs of nerves. The third nerve (motor oculi) supplies all except the external rectus and the superior oblique; it also supplies the levator of the lid, the sphincter of the iris, and the ciliary muscle. The sixth nerve (abducens) supplies the external rectus. The fourth nerve (trochlear) supplies the superior oblique.

BRAIN-CENTRES.—In the substance of the brain, the fibres which are contained in the nerves above named undergo rearrangement and partial decussation. They are connected largely with the gray matter of the corpora quadrigemina and its vicinity, and with higher volitional centres in the cortex; the co-ordination in these centres

appears to be such that all impulses issued to the ocular muscles take effect bilaterally, producing harmonious movements of the two eyes together. The necessity for such co-ordination lies in the fact that, in every normal act of vision, the object looked at is pictured on corresponding points of the two retinæ. The centres are complex as regards their anatomical relations and functions, and are not yet completely made out. The following are those of which we have the most definite physiological evidence:—(a) A centre in the right side of the brain, which combines fibres from the internal rectus of its own side with fibres from the external rectus of the opposite side, and thus produces movement of both eyes to the left. (b) A centre on the left side, which in like manner turns both eyes to the right. (c) A centre which actuates both internal recti, producing movements of convergence; it is closely associated with another centre, which actuates the two lower recti and turns both eyes downwards, and also with others which govern the sphincters of the iris and the ciliary muscles in both eyes, producing contraction of the pupils and accommodation. (d) A centre which receives fibres from the two external recti and produces movements of divergence, or rather of diminished convergence. As will be seen later, there are many forms of disturbance of ocular movements which can only be explained by reference to these compound or associated centres.

The conditions which disturb the movements of the eyes are numerous, and of very different kinds, namely:—(1) Adhesions between the globe and the eyelids, effusions and new formations in the orbit, and even faults in the shape of the eyeball itself, which in a mechanical manner oppose or limit the excursions of the eye in certain directions; (2) faults in the muscles, due to malformation, injury, or to the tissue-changes which occur as the result of excessive or deficient nerve-stimulus; (3) lesions of the nerves at various points between their origin in the brain and their distribution in the muscles; and (4) conditions which disturb the action of the brain-centres. It is evident that any single lesion or fault belonging to either of the first three classes will affect the movement of one eye only, and will throw it out of harmony with its fellow whenever the impaired movement is attempted; the commonest affections of this kind are the paralyses of the ocular nerve-trunks. On the other hand, any condition belonging to the fourth class, whether it be merely a functional overaction, as in

the squint of the hypermetrope, or a suspension of action through a paralyzing lesion, as in the conjugate deviation of hemiplegia, will produce ocular symptoms which are essentially bilateral. So far as they move at all, the two eyes still move in company with each other; to all affections of this class, therefore, the term *concomitant* may be applied. Before discussing these different affections in detail, it will be convenient to speak of certain phenomena which are common to several of them.

DEVIATION OF THE EYE.—In health, the eyes are invariably so directed that the object looked at is pictured on the yellow spot in each retina. If either eye is directed otherwise, it is said to deviate or squint; it has a strabismus. The commonest forms of strabismus are those in which the optic axes converge too much, or diverge, and the same is applied especially to the concomitant varieties—to those, namely, which are produced by excessive or defective action of the centres for convergence and divergence, rather than to deviations due to paralyzing lesions of nerve-trunks; but it applies strictly to the latter also. A less common form of deviation is that in which both eyes are turned involuntarily towards one or the other side, in consequence of a loss of equilibrium in the centres which preside over conjugate movements. See STRABISMUS.

DIPLOPIA OR DOUBLE VISION.—Under certain exceptional conditions, objects are seen double by one eye used alone (monocular diplopia, polyopia); here the fault lies in the refraction of the eye, not in its position. Such cases have no connection with our present subject. In binocular diplopia the two images belong to the two eyes respectively, and when one eye is covered one image disappears.

Double vision indicates a deviation of one or other eye. The image seen in the wrong position belongs to the deviating eye, and is termed the false image; it is usually fainter than the true image because it is formed, not at the yellow spot, but at a less sensitive part of the retina; hence, so, the greater the deviation of the eye, and the greater the consequent displacement of the false image, the fainter does the image become. On this account, the confusion and giddiness produced by double vision are usually greater when the deviation of the eye is slight and the images near together, than when they are widely separated; in the latter case, and, indeed, in most cases of long-standing deviation, the false image is suppressed, the mind

taking no cognisance of the second and erroneous impression. The relative positions of the two images give valuable and very precise indications as to which is the deviating eye, and as to the direction and amount of the deviation. The following rule holds good in all cases:—*The false image and the cornea are displaced in opposite directions.* The reason of this will appear from the following considerations.

We judge of the position of objects from the position of their pictures in our eyes; but, in order that the judgment shall be true, we require to know the position of our eyes. Of this latter we are informed by the muscular sense—in other words, by the amount of the impulse issued by the brain-centres to the muscles. Now if, from any cause whatever, either eye fail to respond correctly to the impulse issued by the brain, we misjudge its position, and, as a consequence, we misjudge the positions of objects pictured on its retina; we project the retinal images as though the eye stood in its right position. For example, supposing the right eye to deviate to the right, while the left eye, obeying the impulse of the will, looks straight forwards at an object directly in front of it. As the cornea of the deviating eye moves outwards, the retina of course moves inwards, so that in this eye the object is pictured on the outer half of the retina instead of at the yellow spot. But if the eye were in its right position, this part of the retina would correspond in direction with objects lying to the patient's left, hence, with this eye, which deviates to the right, he sees things displaced to the left. If, therefore, in any case of doubtful nature, we can ascertain what is the position of the false image in relation to the true image, we shall know what is the direction of the deviation of the corresponding eye. Thus, if the images are crossed in regard to their respective eyes, we know that the deviation is of the opposite kind—namely, one of divergence; if the images are homonymous (each standing to the side corresponding to its own eye), we know that the axes of the eyes are crossed; if the image, instead of standing vertical, appears inclined to either side, we know that the vertical meridian of the corresponding eye is inclined in precisely the opposite direction.

In studying the positions of the double images, we cause the patient to look steadfastly at an object, such as a slip of white paper or a lighted candle, with both eyes open; then, covering each eye alternately,

and telling him to keep looking at the object with the other, we ascertain which eye was properly directed and which was deviating. By causing him to follow the object with his eyes in different directions, we learn in which direction the images separate most widely, and in which they come nearest together; and thereby ascertain in which particular movement the error is greatest, and which muscle is at fault. If the distance between the two images is constant in all positions of the eyes, we know that the affection is of the concomitant form and is not due to a fault in any individual muscle or nerve. A coloured glass placed in the trial spectacle frame before one or other eye, so as to colour the corresponding image, makes the examination easier; it should be placed by preference before the eye which looks straight at the object, for the image seen by the deviating eye is already somewhat the fainter of the two, and, if its intensity be still further lowered by the interposition of the coloured glass, it may probably be altogether overlooked.

Diplopia may be produced in a person with healthy eyes by means of a prism. Rays of light passing through a prism are deflected from their course; hence a prism held before the eye displaces the image of the object looked at on to a part of the retina other than that on which it would naturally fall, and hence double vision. Conversely, diplopia may be corrected by a prism so placed as to counteract the displacement of the image due to the deviation of the eye. A prism deflects rays towards the side corresponding with its own base, and since the actual displacement of the retinal picture in a deviating eye is the opposite of the apparent displacement of the false image in space, the correcting prism must be placed with its base towards the same side as the false image; or, to put the matter simply, let the thick edge of the prism be over the weak muscle. The strength of the prism which corrects the diplopia serves as a measure of the deviation of the eye.

DISEASES AND INJURIES OF THE OCULAR MUSCLES.—These, as distinguished from paralyzes due to nerve-lesions, are not common. In rare instances, one or more of the muscles may be congenitally wanting; in others, abnormal adhesions of the muscle among themselves have been noted; clinically, an accurate diagnosis of such conditions is not possible. Perforating wounds, near to the eyeball, may damage one or other of the muscles so as to permanently impair or annihilate its action; an improperly

performed operation of tenotomy for squint may do the same. The deviations thus produced may frequently be remedied by surgical readjustment of the damaged tendon. See STRABISMUS. Occasionally, by violent injury with a hook or similar object, a muscle is torn away from its posterior attachment, as in a case, seen by the writer, in which a young man jumping over a table came in collision with a gas-burner, which tore the upper eyelid and the ocular conjunctiva, and dragged out the greater part of the internal rectus. Morbid contracture of a muscle occurs as a result of prolonged excessive effort, as in the strabismus of hypermetropia, and loss of tone in the antagonistic muscle, as in paralytic strabismus.

PARALYSIS OF THE OCULAR MUSCLES.—*Causes and Pathology.*—In a large majority of cases, these paralyzes correspond with the distributions of the third, fourth, and sixth nerves. In order of frequency, paralysis of the group of muscles supplied by the third nerve probably stands first; next, and nearly as frequent, paralysis of the external rectus (sixth nerve); lastly, and considerably less frequent, paralysis of the superior oblique (fourth nerve). Isolated paralysis of one of the muscles supplied by the third nerve is comparatively rare; it indicates lesion in a separate branch of the nerve, or in the muscle itself. Syphilis, rheumatism or chill, and injury are the commonest causes of these paralyzes. It is chiefly in the later stages of acquired *syphilis*, much less commonly in the hereditary disease, that they, and especially the third-nerve paralysis, are met with. The lesion may be within the skull, in the sphenoidal fissure, or in the orbital portion of the nerve. Whether it is most commonly of the nature of a gumma, a meningitis, a periostitis, or an inflammation of the connective tissue of the nerve itself, is uncertain. As in the following form, chill to the surface is not infrequently concerned in lighting up the mischief. *Rheumatism* in its acute febrile form is rarely associated with ocular paralysis, but the rheumatism, so-called, which occurs locally, as the result of cold or damp to the surface, is very frequently so. *Gout* must certainly be included as a predisposing cause, for it is especially in those who are immoderate eaters and drinkers, and who show signs of lithiasis, that exposure to cold acts in this way. *Diphtheria* is frequently followed by paralysis of the ciliary muscles (loss of accommodation), less often by paralysis of the external muscles of the eye. *Injuries*

of the skull, especially such as involve fracture of the base, extravasation of blood, meningitis, tumour, abscess, aneurism of the basilar arteries—in short, all changes within the skull which, by pressure or otherwise, can interfere with the nerves at the base of the brain, may paralyse the ocular muscles. Lesions of the nerve-fibres in the substance of the brain are likely to cause paralysis of bilateral form, rather than such as can be referred to one or other of the nerve-trunks. Transient paralyses of the ocular muscles are frequent during the earlier stages of *locomotor ataxy*; the nature of the lesion is uncertain; it is not in direct connection with the changes in the spinal cord.

Symptoms and Diagnosis.—Paralysis of an ocular muscle reveals itself by symptoms which are definite, and can be studied with precision. Movements requiring the action of the paralysed muscle are impaired or lost. We tell the patient to follow the movement of a finger passed in different directions before him, his head being kept in a fixed position, and we notice that while one eye moves to the usual extent upwards, downwards, and to each side, the other is unable to accompany it in a certain direction. Covering the unaffected eye, we then bid the patient do his utmost to follow the finger in this direction, and we find that there is a point beyond which his strongest effort fails to move the eye. The precise position of this point depends upon the completeness or incompleteness of the paralysis, and upon whether movement in the said direction depends solely upon the muscle which is paralysed, or is aided by others.

The eye deviates away from the paralysed muscle. The unaffected eye being in the primary position—that is, looking straight forward at a distant object—the affected eye, although no special effort is demanded of the paralysed muscle, deviates somewhat in the direction of the opponent muscle, the tonic contraction of the latter overbalancing the weakened tonicity of its antagonist. The deviation of the affected eye is called the ‘primary deviation.’ It increases when the patient looks in the direction which demands the action of the paralysed muscle, and decreases when he looks in the opposite direction. It is increased, in cases of long duration, by an actual shortening of the opponent muscle. Again, telling the patient to look at the distant object as before, we bring a hand or a piece of paper in front of the sound eye. By a strong effort, the patient

then brings the affected eye to bear upon the object, and at the same moment the sound eye, moving in the same direction behind the paper, takes up the deviation. This deviation of the sound eye, when the affected eye fixes, is called the ‘secondary deviation;’ it is greater than the primary deviation, for the brain-centre takes no cognisance of the nerve-lesion, and issues an equal impulse to the two sides as in health. Under this impulse the normally innervated muscle acts vigorously, while the paralysed muscle acts feebly.

With both eyes open the patient sees double. This is true, of course, only when the patient actually sees with both eyes; any defect in the visual power of the deviating eye promotes the suppression of the false image. If it should happen that the deviating eye has decidedly the better vision of the two, the patient will contrive by a compensatory position of the head to bring this eye to bear upon the object at which he desires to look; and if the affected muscle be only partly paralysed, a strong impulse will be issued to this muscle, and consequently a secondary magnified deviation of the fellow-eye will be induced, and we shall have the phenomenon of a patient looking straight with a paralysed eye and squinting with a non-paralysed eye. As a diagnostic symptom, *double vision* is of value only when the nature, or the existence, of a deviation would otherwise be uncertain. In paralysis of the fourth nerve, for example, it enables us at once to make a diagnosis, which would otherwise be hardly possible. It also enables us to measure the amount of a deviation, and to accurately judge of its progress towards recovery. The laws which it follows have already been explained. See *Diplopia*. In cases of very slight deviation of the eye, there may be only a confusion or unsteadiness of sight due to an overlapping of the two images, rather than a true diplopia; or diplopia may be elicited only by causing the patient to turn his eyes strongly in the particular direction in which the weakened muscle acts. In many cases the complaint made is rather of giddiness than of double vision, and this is attributable to the patient’s inability to estimate, with certainty, his position in relation to surrounding objects, and especially in relation to the plane of the ground on which he walks.

To avoid the double vision and the giddiness which goes with it, the patient frequently keeps his head turned in a direction which neutralises the deviation of the eye. Thus, if the right eye deviate towards

the right, he will turn his face round towards the left, so that, in looking before him, he may turn the left eye also towards the right, and thus restore parallelism between the two. Or he will adopt the simple expedient of keeping one eye closed; the closed eye will, in most cases, prove to be the paralysed eye, but should this latter have the better vision of the two, its services may be retained, while the other is excluded for the sake of avoiding double vision. Ocular paralysis often declare themselves to the observer, at first glance, by these peculiar positions of the head. The distinctive symptoms of the several varieties of paralysis of the ocular muscles may now be stated briefly; they will be understood by reference to the distribution of the nerves and the general symptomatology already given.

THIRD-NERVE PARALYSIS.—Ptosis, drooping, or complete falling of the upper eyelid; loss of the inward, upward, and downward movements of the eyeball, discoverable on raising the lid and bidding the patient to follow the movements of a finger in various directions. Deviation of the eye outwards, through unopposed action of the external rectus, the deviation being neutralised when the sound eye looks towards the paralysed eye, increased when it looks away from it; also a slight deviation downwards, through unopposed action of the superior oblique. Double vision, when the lid is raised, the images being crossed—i.e. the image belonging to the right eye standing to the left, and *vice versa*; dilatation of the pupil; loss of accommodation. When downward movement is attempted, a slight twisting on the antero-posterior axis, with some movement downwards and outwards, may be observed, from the action of the superior oblique. The false image stands higher or lower than the true image, according as the sound eye is directed upwards or downwards respectively. Its upper end is inclined somewhat away from the sound eye, through the superior oblique having lost its antagonist. Incomplete forms of third-nerve paralysis are frequently met with. Occasionally, one or other of the muscles is affected alone. Isolated paralysis of the inferior oblique is very rare, but well-marked cases have been observed; the symptoms are the counterpart of those of paralysis of the superior oblique.

SIXTH-NERVE PARALYSIS.—Loss of movement outwards beyond the middle line; deviation of the eye inwards, through unopposed action of the internal rectus—i.e. convergent strabismus, increased by efforts

to look towards the paralysed side, decreased by looking in the opposite direction. Homonymous diplopia—i.e. image of right eye standing to the right, image of left eye to the left, or the diplopia is avoided by a compensatory turning of the head towards the paralysed side, or by keeping one eye closed or covered. When the eyes are directed horizontally, the false image is erect, and on the same level as the true image; but, in looking upwards, it stands a little lower than the true image, and in looking downwards it stands higher. These changes are probably due to the actions of the oblique muscles being somewhat modified, as compared with those of the fellow eye, by the deviation inwards.

FOURTH-NERVE PARALYSIS.—Defect of mobility hardly to be discovered, even on close inspection; but the diagnosis made easily from the diplopia. Double vision occurs only on looking below the horizontal line, for only in this direction does the muscle normally come into action. The false image is lower than the true, and inclined towards it; the images are homonymous, each opposite to its own eye. The displacement of the false image increases as the eyes are directed more downwards and towards the affected side. Near to the horizontal line the false image overlaps the true; above the horizontal line vision is undisturbed.

Two or more of the foregoing forms of paralysis may occur together, from lesions involving several nerve-trunks, and they may occur bilaterally from lesions which damage the nerve-trunks of both sides. Bilateral affections, however, are in many cases due to disturbance in a centre common to fibres passing to both sides. The latter diagnosis is indicated when the movements of the eyes are found to be concomitant—i.e. when the two eyes move with equal excursions. An exception to this rule presents itself sometimes in the late stage of a peripheral paralysis, when, though the actual paralysis has entirely disappeared, the eye still deviates through shortening of the antagonist muscle; under these circumstances, since the conductivity of the nerves is equal on the two sides, the movements are strictly concomitant.

Treatment.—In presence of certain of the causes enumerated above, treatment directed especially to the ocular paralysis would obviously be out of place. Uncomplicated paralysees of single nerve-trunks, such as occur from chill, usually tend to spontaneous recovery. Iodide of potassium in moderate doses should, however, be given

In all such cases, whether syphilis be definitely concerned in them or not. Mercury may sometimes be desirable as well. With a view to preventing recurrence, the habits of life and constitutional state, especially with regard to lithiasis, should be attended to. The temple of the affected side should be protected from cold by a silk handkerchief tied round the head. In the early stages, a shade should be placed over the affected eye to remove the diplopia; later, when movement is returning, the weak muscle should be exercised each day by attempts at the movement in question, while the good eye is covered. The recovery of single vision may sometimes be promoted by the use of a prism, which partly corrects the deviation. Electricity effects an immediate and marked improvement in some cases, and, though the immediate result is usually transient, a systematic repetition of the remedy may aid recovery. Galvanism (primary continuous current) is probably more useful than faradism (induced current), because its action is more penetrating, but the latter also gives positive results. Armed with moist sponges, the anode is applied to the neck in the neighbourhood of the mastoid process, the cathode over the closed eyelids. The sitting should not last more than two or three minutes, and should be repeated daily or on alternate days. The strength of the current must be such as not to cause pain, and being especially necessary in the case of the continuous current. Operative treatment is only justifiable when all improvement has been at a standstill for some months; then, if the paralysed muscle have recovered some power, but deviation persists in consequence of shortening of the antagonist, tenotomy of the latter, and sometimes advancement of the former, may be performed with advantage. These operations are described in connection with STRABISMUS.

CONCOMITANT AFFECTIONS.—This group includes the common convergent strabismus of hypermetropia, the divergent strabismus of myopia, conjugate deviations, ophthalmoplegia externa, nystagmus, and some other varieties of motor disturbance depending on excessive or defective action of the brain-centres. The common characteristic is that there is a similar fault of movement in both eyes, the disturbing cause having effect either in the centres which govern bilateral movements, or at any rate so high up in the nerve-mechanism as to involve fibres belonging to both sides. It will be convenient to speak here of the

paralytic conditions, as they are allied with the diseases described in the foregoing paragraph. See STRABISMUS.

Conjugate Paralysis.—Both eyes deviate to one side and cannot be turned towards the opposite side. The causes of this affection are the same as those of other central paralyses. It is generally but not always associated with hemiplegia. If the eyes are turned to the right, the lesion is situated in the right side of the brain and involves the centre which normally turns both eyes towards the left. The deviation is due to the unopposed tonic contraction of the corresponding centre in the left side. Conjugate deviation to the right, therefore, goes with left hemiplegia; the patient cannot look to his paralysed side. It is the motor analogue of the sensory symptom, hemiopia, in which a lesion of the right side of the brain blinds the right half of each retina, and the patient cannot see to his paralysed side (Hughlings Jackson). The right halves of the two retinæ in conjunction constitute the visual organ for the left side; hence a lesion on the right side of the brain, whether it cause hemiplegia, conjugate deviation of the eyes, or hemiopia, tells in its results always in the same direction. Although the two recti which are concerned in this paralysis are totally inactive for conjugate movements, they may remain active for convergent and divergent movements; thus, in a case observed by the writer (*R. L. Ophth. Hosp. Reports*, vol. viii. p. 185), neither eye could to the smallest extent follow the movement of an object moved laterally before the patient's face, but both eyes performed movements of convergence when the object was moved from a farther to a nearer point, in line with the oblique direction of the eyes. Conjugate paralysis may rapidly disappear, or it may be of long duration. In several cases observed by the writer, the recovery of movement has been unsymmetrical on the two sides, the eye turned outwards returning to its normal position sooner than the eye turned inwards, so that a convergent squint resulted.

Paralysis of Convergence.—The power of converging the eyes is lost, and there is a fixed divergence, which the strongest effort on the part of the patient is unable to diminish. The fixity of the divergence distinguishes the disorder from ordinary divergent strabismus, such as occurs in myopia and after an excessive tenotomy, for, in the latter, the divergence diminishes during efforts of accommodation for a near object. Yet there is no true paralysis of the internal

recti, for conjugate movements to either side are performed with ease. This eliminates the possibility of lesion of nerve-trunks, and indicates a lesion in the centre for convergence or of strands connected therewith.

Paralysis of Divergence.—This is a counterpart of the foregoing. The eyes maintain a fixed convergence, which does not diminish on looking at a distant object, and which is thereby distinguished from the ordinary convergent strabismus of hypermetropia; yet the external recti are not paralysed, for conjugate movements to either side are performed freely. These conditions are rare. In a case of each form observed by the writer (*op. cit.* vol. ix. pp. 22, 428), the paralysis involved not only the movements of convergence and divergence respectively, but also those movements which, as before stated, appear to be anatomically associated with these. In the one case, there was total loss of convergence, downward movement, accommodation, and contraction of the pupils in both eyes; in the other, there was total loss of divergence and upward movement in both.

Ophthalmoplegia externa is a term used to indicate loss, partial or complete, of all movements in both eyes. It implies a central lesion of a more extensive kind than those which cause the paralyzes of particular movements above described. It represents the simultaneous occurrence of all these forms. Accommodation and contractility of the pupils may, however, remain intact.

Nystagmus. See NYSTAGMUS.

Spasm.—It is probable that each form of bilateral deviation, described above, may occur from spasmodic action as well as from paralyzing lesion. Over-action of the convergent centre, associated with accommodative spasm, occurs in some cases of hysterical paroxysm. It is the cause also of some cases of concomitant strabismus, in young children who are not hypermetropic. The commonest form of deviation from over-action of this centre is that which results from hypermetropia. See STRABISMUS.

PRIESTLEY SMITH.

ODONTOMA, or TOOTH TUMOUR, is the name originally given by Broca to the group of cases in which the tumour consists of tooth-elements more or less hypertrophied. The majority of these are outgrowths from the pulp of well-formed teeth, or at least have their connection with the teeth well marked, and are, therefore, of interest, principally, to those engaged in dental surgery.

There is one form of odontoma, however, which is strictly surgical, since it is apt to give rise to serious mistakes in the diagnosis and treatment of one form of tumour of the jaw. This depends upon some modification of the germs of one or more of the molar teeth of the lower jaw, before the development of the cap of dentine, which leads to the formation of an irregular mass of dental tissues, in no way resembling a tooth in shape. These cases are very rare, and occur only in the lower jaw. The symptoms are those of a dense tumour expanding the bone, in which there is no pain, unless the mass should interfere with the development of the wisdom-tooth, or be mistaken for a misplaced tooth or a sequestrum, when acute inflammation may be excited in the jaw itself by ineffectual attempts at removal. Very eminent surgeons have been misled by these cases, and have unnecessarily sacrificed portions of the lower jaw, when, as experience has shown, enucleation of the growth could invariably have been undertaken with success. The writer recently had a case of the kind under his care, in which persistent efforts to remove what was supposed to be an impacted tooth had given rise to so much inflammation about the jaw and gums that, when the writer was first consulted, he believed the patient to be suffering from a rapidly growing tumour of the interior of the jaw, and recommended removal of a portion of the bone. Fortunately, on the subsidence of the inflammation, the case more resembled one of necrosis, and on attempting to search for and remove a sequestrum, an odontoma measuring $1\frac{1}{4}$ by $1\frac{1}{2}$ inch, and weighing 315 grains, was readily enucleated. This consisted of dental tissues irregularly arranged, and represented one or two molar teeth.

Displacement of otherwise healthy and well-formed teeth may give rise to enlargement of either jaw, and even supernumerary teeth have been known to form distinct tumours connected with the maxillary bones. Such cases must necessarily be very difficult of diagnosis, and are best treated by exploration before any serious mutilation is undertaken.

CHRISTOPHER HEATH.

CEDEMA is the result of undue exudation of serum or liquor sanguinis into the interstices of connective-tissue and lymphatic vessels. There are several possible factors, one or more of which may be involved in a given case. Foremost, on account of its frequency and extent, is

increased pressure in the capillaries. This, in turn, may be the consequence simply of venous obstruction, as when a vein is ligatured, varicosed, occluded by a clot, or pressed upon by a tumour or aneurism. Or, the feeding arteries may be flooded from paralysis of the vaso-motor nerves, a condition occasionally seen when the lower extremities are œdematous in fracture of the spine, even in the absence of renal or heart disease, or any extrinsic cause of obstruction to the flow of blood. Another illustration of this variety of œdema is afforded by the rapid but transient swelling which follows sharp irritation of the skin. Cardiac feebleness, again, may be so marked that the inertia of the column of blood in the veins is with difficulty overcome. The back-pressure on the capillaries, even if it does not lead to stagnation therein, is sufficient to account for very considerable exudation of serum. Familiar examples of this are afforded by the œdema of the legs in persons convalescent from the acute fevers, or weakened by some constitutional malady like cancer, or reduced by protracted pyrexia, as in phthisis. 'Œdematous erysipelas' of old people, the subjects of feeble circulation, is another instance in point, and, inasmuch as one cause of the œdema is abiding, there is permanent enlargement of the part, which becomes more solid with the lapse of time.

Now, since the pressure in the *lymphatics* reciprocates that in the blood-vascular capillaries, it will easily be seen that blocking of the former may, of itself, entail obvious transudation of fluid into the areolar spaces. *Elephantiasis*, as met with in Orientals, is largely due to distension of the lymphatics, which are infested with the parasite *filaria sanguinis hominis*. Again, there are grounds for the belief that coagulation of lymph in its accustomed channels forms part of the pathology of *phlegmasia alba dolens*. On the other hand, when the hindrance to the venous circulation is great, the surrounding lymphatics are dilated. Amussat found this a frequent occurrence in varices.

Nor must the state of nutrition of the blood-vessels be ignored. The capillaries are subject, with the other tissues, to fatty atrophy from disease, whether it be from palsy of the limbs or from forced rest, as in fractures. Sustained high temperature causes a similar change, and this is another explanation of the œdema met with after the specific fevers and other acute febrile disorders. In albuminoid disease, the alteration in structure of the coats of the

small arteries facilitates the transudation of serum.

The composition of the blood must have some influence on the exosmosis, for it is well known that the rate of dialysis varies directly with the amount of crystalloid elements contained in a given fluid.

In certain cases, œdema appears to be to some extent compensatory to the removal of the normal constituents of the tissues; thus, it is not rare to find adipose tissue infiltrated with serum coincidentally with the absorption of fat from the cells, in wasting diseases like phthisis.

It should be borne in mind that a general tendency to dropsy causes the swelling associated with a local inflammation to appear out of all proportion to the intensity of the irritation—e.g. extensive œdema at the site of an eczematous patch at once raises the presumption of albuminuria, which may not have been previously suspected either by the surgeon or patient.

VARIETIES OF ŒDEMA.—It is customary to divide ordinary cases of œdema into two groups—(1) *simple or serous*, and (2) *inflammatory or plastic*. The former occurs in renal and cardiac disease, and in many forms of local obstruction to the circulation. Simple serum differs from inflammatory fluids in that it contains no fibrinogen, for it does not coagulate spontaneously on exposure, nor on the addition of red blood-corpuscles. It is highly albuminous. Tissues infiltrated with serum pit deeply on pressure. They are paler than natural, and look glistening and jelly-like. On section or puncture the fluid rapidly escapes, being expressed by the elasticity of the connective-tissue fibres between which it is contained.

Inflammatory œdema, or the 'hydrops fibrinosus' of Vogel, varies within very wide limits both as to its extent and solidity. The looser the texture of the tissue infiltrated the more marked is the swelling. It is quite phenomenal in the scrotum, where it occurs from local causes—wounds, extravasation of urine, &c.—and as a sequel of scarlet fever and smallpox (Erichsen).

Acute œdematous laryngitis, especially when it follows perichondritis, is of grave clinical significance, owing to the rapidity of the exudation and the encroachment of the swelling on a vital part of the economy. Chemosis of the conjunctiva is another example of sudden development of œdema.

The fluid may be so highly fibrinous as to coagulate quickly and firmly. This is one form of 'solid œdema.' On the contrary, it may remain in the liquid state two

or three days in a limb that has been amputated for cellulitis.

Renal and cardiac disease diminish the tendency to coagulation by lessening the amount of fibrinogenetic substances in the fluid, which is then in fact a mixture of serous and plastic effusion. This combination is not uncommonly met with in the lungs of patients who have succumbed to renal disease. The lung-texture is lacerable from the pneumonic change, and loaded with serosity from the 'serous apoplexy.' It may here be noted that simple serous effusion, within the ventricles of the brain and beneath the arachnoid membrane, presents a somewhat cloudy appearance, which is commonly mistaken for evidence of meningitis. On dissection, however, it is found that the pia mater can be readily stripped from the cerebral substance, and the convolutions separated without tearing.

Œdema, both simple and inflammatory, is seen in connection with fractures of the bones, where it is due partly to the rupture of vessels and the pressure of blood-clot, and partly to exudation the result of injury to the tissues. It may be considerably increased by the injudicious application of bandages and splints, when the tension on the capillaries may become so great as to lead to sloughing of the soft tissues.

Malignant anthrax œdema.—In some cases of anthrax or charbon, where the typical 'pustule' is absent, there is firm gelatinous œdema, especially about the eyelids; and in another manifestation of the disease, called *internal anthrax*, there is commonly brawny œdema of the cellular tissue of the neck.

Myxœdema.—The chief anatomical change in this affection is a conversion of the gelatin and chondrin of the connective-tissue—particularly of the hands, feet, and face—into mucin, a reversion as it were to the embryonic condition. The skin looks swollen and has a waxen appearance. There is little or no pitting on pressure unless the kidneys are diseased, when ordinary serous œdema may be added to the more special features of the case.

Duration of Œdema.—Œdema may be so transient as to last only a few minutes, as when a wheal is produced by flagellation. Or it may be long abiding from (a) continuation of the cause—e.g. varicosity of the veins of the leg and cachectic states of the body; (b) permanent occlusion of blood-vessels and lymphatics—this is sometimes seen in 'white leg'; (c) coagulation and subsequent organisation of the inflammatory effusion.

The *density* of the swelling varies as the amount and coagulability of the fluid effused and the time it remains unabsorbed. The higher grades are designated '*solid œdema*,' for there is little pitting on pressure, and change of position has very slight effect upon it.

Treatment.—The chief indication is to remove all causes that impede the circulation. In the varicose œdema of the legs, pressure by means of an elastic bandage evenly and continuously applied is the method to be adopted.

In most cases, considerable aid may be obtained by elevating the limb sufficiently to allow of the ready return of blood from the veins, without materially increasing the resistance in the arteries. This plan is especially applicable to fractures of the leg, where pressure cannot be safely employed.

In long-standing cases—e.g. those due to wide-spread thrombosis of the veins—massage, with after-pressure, will help in the absorption of the exudation. This plan is excellent if systematically carried out.

In acute inflammatory œdema, where there is danger of sloughing, free incisions should be made; and where this is not practicable, as in the throat, the part should be scarified.

Serous œdema from renal or cardiac disease, which cannot be overcome by posture and the administration of drugs, may be relieved by a number of fine punctures made in the skin with a darning-needle, or Southey's tubes may be inserted.

AUGUSTUS J. PEPPER.

ŒSOPHAGOTOMY is required for the removal of foreign bodies impacted in the upper part of the œsophagus, when all other methods of extraction have failed. It has been also performed to facilitate internal division of a stricture of the œsophagus.

The patient should be placed upon his back with the head and shoulders slightly raised, and an anæsthetic should be given. The face should be turned to the side opposite to that on which the incision is made. This should be the left side, unless there is a decided projection, caused by the foreign body, to be felt upon the right side.

An incision, three to four inches long, should now be made through the integuments along the anterior border of the left sterno-mastoid, with its centre corresponding to the position of the foreign body. The skin, superficial fascia, platysma myoides, and deep fascia will be thus divided; the sterno-mastoid will be exposed, and it should be drawn outwards by a retractor.

The carotid sheath now comes into view, with the descendens noni nerve lying upon it, and the omo-hyoid muscle crossing it. The sheath should be carefully separated by a blunt director or the finger from the trachea, the thyroid body, and the larynx, with the depressors of the hyoid bone which cover them. The omo-hyoid muscle should be drawn outwards, or, if it is found to be in the way, it may be divided. Care should be taken to avoid wounding the superior and inferior thyroid arteries, and the recurrent laryngeal nerve, which lies in the groove between the trachea and the œsophagus. The superior and middle thyroid veins may have to be ligatured and divided.

When the carotid sheath and its contents, together with the sterno-mastoid and the omo-hyoid, have been drawn outwards by a large blunt retractor, and the trachea with the overlying structures has been drawn to the opposite side in a similar manner, the œsophagus and lower part of the pharynx will come into view. If the impaction be low down, it may be also necessary to divide a few of the outer fibres of the sterno-hyoid and sterno-thyroid muscles. A long-handled curved forceps should now be introduced through the mouth, and when it has reached the foreign body the blades should be expanded, so as to indicate clearly the part of the œsophagus which has to be incised. A longitudinal incision should now be made in the œsophageal walls, of a size determined by that of the foreign body. If it should be found to be too small, it may afterwards be enlarged upwards or downwards, as may be most convenient. All vessels that bleed should at once be tied, firstly, in order that the parts may not be obscured by blood, and secondly, to prevent the cellulitis which might follow the decomposition of blood extravasated through the tissues. As soon as the opening has been made, the finger should be introduced and the exact position of the foreign body ascertained. It may then be laid hold of by appropriate forceps and cautiously removed.

If the impaction is quite recent, and the œsophagus free from inflammation or laceration, it may be safe to carefully bring together the edges of the œsophageal wound with chromicised catgut sutures, while the edges of the external wound are left open for the discharge of blood and serum, and of any foreign material which may escape through the walls of the œsophagus. In many cases, however, it is advisable to leave the wound of the walls of the canal open, as well as that of the superficial

structures. For a week or more after the operation the patient must be fed with a small œsophagus tube, which may be left in, or if the patient cannot bear this, it may be passed for every meal. Nutrient enemata may also be necessary for a few days. Later on, the patient should be allowed to begin cautiously the swallowing of liquid food. There will often be a small fistulous opening for a few weeks, but this usually closes without any trouble.

ŒSOPHAGOSTOMY is performed in the same manner as the operation just described, except that the incision should be as low on the left side of the neck as practicable. The œsophagus will have to be found without the guidance of the forceps or sound introduced by the mouth, and after it has been found and opened, the edges of the incision, and especially the margins of the mucous membrane, should be carefully stitched to the skin at the lower extremity of the external wound. In the after-treatment, great caution must be exercised in introducing the feeding tube, to avoid laceration of the wall of the œsophagus, or the passage of the instrument by its side into the adjacent tissues.

N. DAVIES-COLLEY.

ŒSOPHAGUS, Injuries and Diseases of the.—FOREIGN BODIES of various descriptions are apt to become impacted in the œsophagus, such as masses of imperfectly chewed food, bones, and especially fish-bones; pins, coins, and other metallic substances; and lastly, artificial teeth, which, with the plates to which they are attached, have, of late years, frequently been swallowed, and after lodging in some part of the canal, have become firmly fixed by the hooked projections or 'bands' with which they are provided. The point of impaction is usually one of the three natural constrictions of the œsophagus, and especially the highest, which is at the upper extremity, just below the level of the cricoid cartilage; the second constriction is three inches lower, where the œsophagus deviates slightly to the right, to pass under the arch of the aorta; and the third is where its lower extremity traverses the diaphragm.

The *symptoms* will vary in some degree with the position of impaction. If this is high up, there may be considerable dyspnœa and coughing from laryngeal irritation. Pain may be complained of at the spot where the body is fixed, or it may be referred to some other region, such as the notch of the sternum. If the body is in the cervical portion of the canal, there will

probably be some tenderness upon external pressure. Swallowing is usually difficult and painful, and it may be impossible; or, after the food has been swallowed, it may be retched up again. When the obstruction is complete, there will be a constant expectoration of saliva and mucus. In some instances, foreign bodies have remained for a long time without giving rise to any serious symptom. Usually, however, ulceration supervenes, and its presence will be indicated by the blood and pus retched up by the patient. Abscesses may follow in the adjacent tissues, the air-passages may be opened, and inflammation set up in the lungs; or some great vessel, such as the aorta, may be perforated, and give rise to sudden and fatal hemorrhage. In rare instances, it has happened that the ulceration has loosened the impaction, and permitted the foreign body to be ejected through the fauces, or to pass onwards into the stomach.

The *diagnosis* is sometimes rendered difficult by the fact that, after a foreign body has been dislodged, some abrasions may have been left, and the uneasy sensation still remaining may convey the impression that no change has taken place in its position. If the body is large, and not entirely in the œsophagus, it may be possible to reach its upper extremity by means of a finger inserted through the fauces, or its exact situation may be detected by some projection to be felt externally. When it is high up in the gullet the laryngoscope will also be of service, but in many cases it will be necessary to rely upon the passage of a probang furnished with a smooth metallic or ivory bulb, by which contact with any hard substance will be communicated to the fingers. If there is any suspicion that a previously impacted body has been dislodged, a careful examination should be made of all vomited and fecal matters.

Treatment.—Foreign bodies in the œsophagus must be removed by the mouth, or pushed onwards into the stomach, or in rare cases it may be necessary to cut down upon them in the cervical portion of the canal. If the body be high up, a sudden jar, such as a slap on the back, may dislodge it into the pharynx, whence it will probably be ejected by the spontaneous efforts of the patient. The vomiting which occurs during the examination of the parts is also sometimes effectual in displacing the foreign body, and emetics have been given by the mouth, or where this was impossible, by the rectum or subcutaneously, with the same object. Such an expedient,

however, would only be justifiable if the body were small and recently impacted, for there is some danger of rupture of the œsophagus during the efforts of vomiting. If the body is a mass of solid food, or if, though hard, it is smooth and not very large, it may be gently pushed on by means of a sponge probang into the stomach. The same plan may also be resorted to when a sharp or angular body has become impacted low down, and has resisted repeated efforts to extract it. Should such a body have entered the stomach, it will be necessary to keep the patient quiet, and to give him plenty of solid bulky food with but little fluid, so as to secure the safe transit of the foreign body through the intestines.

When, however, the impacted foreign body is hard, angular, and of considerable size, and especially when it is fixed high up, we should endeavour to remove it with the long-handled curved forceps. Coins may be extracted by means of a special apparatus, consisting of a blunt flat hook attached by a thin slip of steel to the probang. They are usually impacted high up, with their flat surfaces directed forwards and backwards. For pins, fish-bones, and similar substances, the dilating horsehair-probang is of great value. This should be introduced into the gullet for a short distance beyond the obstruction, and then, after expansion, be gently withdrawn. If this instrument be not at hand, a good substitute may be made by attaching a skein of thread to the end of a flexible bougie, so as to entangle the body in the numerous loops which are thus formed. Fish-hooks have been removed by means of a perforated bullet or ivory ball threaded on the gut, and then pushed down so as to fill the concavity between the barbed point and the shank.

If, however, all these methods have failed, and if the foreign body remains in or near the cervical portion of the œsophagus, operative interference should at once be resorted to, without waiting for the complications which the ulceration of the walls of the canal will soon produce. See *ŒSOPHAGOTOMY*. In some cases, in which dyspnoea is an urgent symptom, it may be necessary to perform laryngotomy before attempting to extract the foreign body. After it has been removed, the patient should be kept quiet, and fed with milk and other unirritating liquids.

INJURIES of the œsophagus most frequently occur from the accidental or suicidal swallowing of strong acids or caustic alkalies. The patient is usually much col-

lapsed, and there may be lividity and severe dyspnœa from laryngeal spasm. The tongue, fauces, and pharynx are white and wrinkled, or red and swollen, according to the nature of the material swallowed. There is intense burning pain in the throat and along the gullet. Vomiting may occur, and the ejected matter will consist of altered blood and shreds of mucous membrane, mingled with the contents of the stomach. At a later period there will be frequent retching up of thin, watery, blood-stained mucus. If the stomach was empty when the material was swallowed, the inflammation and perforation of its walls will usually prove speedily fatal. If, however, the œsophagus has received the chief injury, sloughs will come away and a stricture will gradually form, which may lead to the slow starvation of the patient.

Treatment.—When the patient is able to swallow, the appropriate antidotes should be at once administered to neutralise the action of the poison. *See* ACIDS, ALKALIES, Swallowing of. The patient must be kept quiet, and fed with nutrient enemata, to which small quantities of tincture of opium may be added. When the acute inflammatory symptoms have begun to subside, liquid nourishment may be given by the mouth, and bougies should be passed to prevent contraction, or in some cases a soft tube may be retained in the canal, and the patient fed through it. The surgeon should also be prepared to perform laryngotomy, if the dyspnœa from œdema glottidis or spasm should threaten suffocation.

Serious and even fatal results have occasionally followed other forms of injury. The performers of so-called sword-swallowing have sometimes died suddenly from the perforation of a great blood-vessel or of one of the serous cavities of the thorax; or acute and sometimes fatal inflammation of the coats of the œsophagus has resulted from its repeated irritation. In violent efforts of vomiting, the gullet has been lacerated or completely torn through. It has also been wounded from without by stabs or incised wounds of the neck (*see* THROAT, Injuries of the), and more rarely in those of the thorax. In all these cases, rest with a milk diet will be necessary, and in the more severe cases, especially when there is perforation of the coats, the patient must be restricted to nutrient enemata.

DISEASES.—With the exception of stricture, the diseases to which the œsophagus is liable are rare and comparatively trivial. It is sometimes the seat of a transient

catarrhal inflammation, of which the chief symptoms are pain and difficulty in swallowing. Diphtheritic exudation, aphthous ulceration, and submucous abscesses are occasionally observed. In tertiary syphilis we may get gummatous deposits and ulceration, which are very likely to lead to a subsequent stricture. After death, not infrequently warty growths are found in the mucous membrane, or cysts in the submucous tissue, or myomata in the muscular coats; but these very rarely cause any serious inconvenience during life. In rare instances, congenital malformations have been recorded, such as an imperforate condition, which is of course rapidly fatal; or a diverticulum, forming a pouch in which food may collect. This has usually been in the cervical region, and it has sometimes been indicated during life by the formation of a visible swelling after a meal, which could be emptied by external pressure. Similar pouches are also said to occur lower down, as the result of the perforation of the tube from abscess of a bronchial gland.

STRICTURES of the œsophagus may be classed under three heads—(1) Spasmodic, (2) simple, and (3) malignant. Dysphagia may also be occasionally due to causes external to the gullet. An enlarged gland or tumour, or an aneurism, may sometimes compress the canal, and so produce the symptoms of stricture. As a rule, however, a bougie can be passed into the stomach in these cases, and if the obstruction be situated in the neck, its character can be ascertained by external examination; if in the thorax, an exact diagnosis will be difficult, except sometimes in the case of aneurism, which may be recognised by auscultation or a comparison of the radial pulses. *See* DYSPHAGIA.

1. *Spasmodic stricture* is usually, but not invariably, met with in hysterical women, and it may be associated with a slight amount of genuine contraction.

2. *Simple stricture* is, almost always, the result of cicatrization after the destruction of the coats of the œsophagus by some escharotic agent. Occasionally, however, it is set up by some other form of ulceration, such as that which follows syphilitic deposit or the temporary impaction of a foreign body. In a few instances, a contraction of some part of the œsophagus, and especially of its cardiac end, appears to have been congenital, or to have occurred, without any obvious cause, in very early life. This may consist of a mere fold of the mucous membrane, or it may affect all the structures of its walls.

3. *Malignant stricture* is by far the most common form, and it is nearly always epitheliomatous. Beginning in the mucous membrane, the disease spreads to the subjacent coats and sometimes to the neighbouring glands. Colloid, scirrhus, and other forms of tumour have been recorded. The disease may be annular, or it may be confined to one side of the tube.

The chief *symptom* of stricture will be dysphagia. This is at first slight, the patient having to cut up or bite his food smaller, and being a little slow in swallowing it down. Soon there is complete inability to eat solid food, which is either ejected by retching, or else a piece becomes fixed in the tube for some time, and prevents the passage even of liquids, until it is dislodged from its position. In some instances, such a stoppage comes on suddenly and is the first indication of the disease. The patient has now to subsist entirely on fluids, and he gradually emaciates. There is frequent vomiting or retching of frothy mucous fluid, in great measure derived from the unswallowed saliva, and if there is ulceration, this will be accompanied by small quantities of stinking pus and blood. There may be pain in the gullet, or it may be referred to some other part, such as the notch of the sternum. At first the sense of hunger is great, but often, in the later stages, the patient becomes apathetic and loses this craving. Finally, the disease is usually fatal by starvation; but, in the malignant form especially, death often occurs from some perforation of the air passages, which allows food to pass into the lungs and set up pneumonia, or some great vessel may be opened by ulceration, and prove fatal by profuse hæmorrhage.

The *spasmodic* form may be suspected in neurotic patients, where there is but little emaciation or loss of strength. The inability to swallow is apt to be inconstant, and there is not the intense craving for food which is characteristic of genuine stricture. Usually, a full-sized bougie can be passed with or without the aid of an anæsthetic.

When, however, there is a distinct history of continuous dysphagia, accompanied by progressive emaciation and a constant desire for food, the diagnosis will lie between *simple* and *malignant* stricture, and will depend chiefly upon the history of the case, the age and sex, and to some extent also upon the general appearance of the patient. If the obstruction is high up, an external examination may reveal some swelling or induration of the

neck, from cancer of the œsophagus or its lymphatic glands. In most cases of malignant stricture the disease begins without any assignable cause. The patient is generally of the male sex, and over forty years of age. There may be some appearance indicating a special cachexia, but this will be difficult to distinguish from the emaciated condition dependent upon the privation of food. In the simple form there will be the history of some cause, such as the swallowing of a corrosive substance, or the impaction of a foreign body; or the patient may have been the subject of syphilis, of which traces may be looked for upon the skin, the tongue, and the fauces. In the rare cases in which the contraction has existed from birth or early childhood, there will probably be a history of slowness in swallowing, and of regurgitation, or, so to speak, rumination of the material swallowed.

In all cases of stricture, the diagnosis is much helped by the use of a flexible bougie about three-eighths of an inch in diameter. The mouth of the patient should be widely opened, and the head thrown back. The instrument, after being well softened in warm water and oiled, should be passed with the operator's right hand, his left index finger guiding it into the pharynx and past the orifice of the glottis. Frequently, a slight hitch is felt when the bougie has reached the notch of the sternum or a little lower. This may be due to the change of direction of the œsophagus at this point, corresponding to the change from the anterior convexity of the cervical spine to the concavity of the dorsal region. If the œsophagus be healthy it is only necessary to make the patient bend the head forwards, and the instrument will slip on till it reaches the stomach, and is stopped by coming into contact with the greater curvature of that organ. If more than sixteen inches of the bougie are found to have passed the front teeth, we may be certain that the whole of the gullet has been traversed. If, on the other hand, the instrument be stopped before this length has passed, and if after slight withdrawal or rotation, or after flexion of the neck as above described, the instrument fails to penetrate further, there is probably a stricture at the point reached, and the position of the stricture is indicated by the length of the bougie which has been inserted. The exact point in the œsophagus is easily ascertained by subtracting six inches from the amount, that being the average distance of the upper

end of the canal from the front teeth of the adult.

On withdrawing the instrument, it should be carefully examined for indications of ulceration, which it may afford by a smear of blood or pus upon its surface. In many cases it will be necessary to use bougies of other sizes and shapes, and in some it may be desirable to have the assistance of an anæsthetic, to overcome the spasm which resists the introduction of the instrument. Some information as to the position and narrowness of the stricture may be also obtained by auscultation with a stethoscope placed on the left side of the trachea in the neck, or to the left side of the spines of the vertebræ in the back.

Treatment.—In the *spasmodic* form, nervine tonics and sedatives should be given, and a bougie should be passed from time to time; the local application of galvanism is also beneficial.

In the *simple* form, early recourse should be had to dilatation by bougies, even before the granulating sores which precede the contraction have completely healed. The instrument, when passed, should be left in for a few minutes daily, and cautious attempts should be made to introduce larger sizes, until the full calibre of the canal has been restored. In some cases it is possible to introduce only a fine catgut bougie. If so, this may be used as the guide for passing gum elastic tubes of various sizes, which may be left for several days in the œsophagus, the patient meanwhile being fed through the tube. Great care is necessary in the introduction of bougies, for there is often a pouched condition of the gullet above the contraction, which renders the upper orifice of the stricture difficult to find. At the same time the walls of the pouch are thin and soft, and they have sometimes been perforated with fatal results. Until the œsophagus has been dilated, the patient should be fed with fluid diet, for otherwise great distress may be produced by temporary closure of the stricture with a morsel of solid food.

Internal Œsophagotomy has been occasionally performed as a help to dilatation, but there is danger of cutting beyond the walls of the canal, and opening some large vessel or one of the adjacent serous cavities; while the cases, in which alone it can be practised, are of permeable strictures, and may be more safely treated by bougies.

If, after repeated efforts, it is found impossible to pass a bougie, even with the help of an anæsthetic, and if the ability to

swallow even liquids is gradually diminishing, while the patient steadily loses weight and strength, it will be necessary to resort to *GASTROSTOMY*, which has, as might be expected, yielded much better results in this than in the malignant form of stricture. It is important to perform this operation while the patient has still strength enough to bear the diminution of food necessitated during the establishment of the artificial opening, as well as to permit of the formation of firm adhesions between the stomach and the parietes. When formed, the gastric opening will usually require to be permanent, but, in some instances, the rest thus given to the stricture has led to its amelioration; the power of swallowing has returned, and it has been found possible to close the opening.

Œsophagostomy has also been practised in a few cases. It is, however, only applicable where the stricture is limited to the upper part of the canal, and, even then, the dangers which attend it make the operation decidedly inferior to gastrostomy.

When the stricture is near the cardiac orifice, Signor Loreta has recently suggested and successfully carried out another operation. Having opened the abdomen and drawn a part of the stomach out of the wound, he makes an incision into it, and through the opening introduces a dilator into the lower part of the œsophagus, and, after forcibly dilating it, withdraws the instrument, sewing up the wound of the stomach wall, and returning the stomach to the abdominal cavity.

In *malignant* stricture, the treatment can only be palliative, except in the rare instances in which the disease is confined to the upper part of the canal; in which case it may be possible to remove the growth, and attach the upper end of the canal to the edges of the lower part of the wound, so as to provide an opening for the reception of food. See *Œsophagostomy*, under *ŒSOPHAGOTOMY*.

After the diagnosis has been made, so long as the patient is able to take plenty of liquid nourishment, it is unwise to use instruments, for fear of perforation. As soon, however, as the passage of liquid food becomes difficult, and the patient begins to waste, a flexible tube should be passed by the mouth or nose through the œsophagus into the stomach, and there retained, so as to allow of the regular feeding of the patient. As a rule, the stomach tolerates the presence of the tube, but if any symptoms of gastric disturbance arise, the tube may be withdrawn a short distance, so as

to place its lower end in some part of the œsophagus below the stricture, but out of the cavity of the stomach. Mr. Charters Symonds has recently suggested an improvement upon this plan. A gum elastic tube, furnished with a funnel-shaped upper expansion, is passed through the stricture until its dilated extremity rests upon the top of the stricture. It is inserted on the end of a conical bougie, or by a special introducer. The tube keeps the stricture from closing, and its calibre is sufficient to allow a free passage to properly prepared food, which can now be swallowed by the patient in the ordinary way. The saliva also and mucus, which, when the longer tube is kept in, well up into the mouth and have to be expectorated, are enabled by this method to pass onwards through the tube into the stomach. A piece of silk thread is attached to the upper rim of the tube, and brought out at the corner of the mouth, to be fixed by a loop round the ear. When it is desired to examine or change the tube, it is drawn up by means of the silk thread. After inspection it can readily be returned to its old position, or a larger one may be introduced in its place, as considerable dilatation results from the continuous pressure of the tube.

When, however, bougies cannot be passed, or if passed, cannot be retained, increasing weakness and wasting may render operative interference necessary. The most generally applicable is gastrostomy. In some cases in which the disease is situated high up, it has been proposed to establish an artificial opening in the lower part of the neck (see *Œsophagostomy*, under *ŒSOPHAGOTOMY*), but even in these cases the operation of gastrostomy is preferable.

N. DAVIES-COLLEY.

OLD AGE.—It would be useless to attempt to define in years the period of life which, in the study or the practice of surgery, shall be called old age. Its essential characteristics are the degenerations prevalent in all the structures and increasing in them. But these do not begin at nearly the same age in all persons or in all parts of the same person; and their advent and progress are so dependent on inheritance, previous health, occupation, and the other external conditions of life that, in practice, it is often better to estimate a patient's age by his appearance and physical capacity than by the years since his birth. It will be in this view that old age will now be spoken of in its relation to each of the chief subjects of general

surgical pathology, and first in its relation to injuries, including surgical operations.

The risks of shock, especially if it be prolonged and attended with enduring pain, increase with advancing age in the same measure as the accumulations of degenerative changes and the effects of previous diseases. The recovery from shock is often slow and interrupted by relapses, and sometimes old people who, in a calm life, have been deemed healthy, die very soon after the shock of injuries which to the younger might have been trivial.

Hæmorrhage is not especially dangerous to the aged, unless they be very infirm or unsound. This used to be often proved when free venesection was customary, and is shown in the facility of recovery from occasional large bleedings from the prostate, and from the epistaxis to which some gouty old persons are subject. Anæsthetics are generally well borne: but it is a good rule to use chloroform rather than ether, because of its lesser tendency to excite bronchial irritation or pulmonary congestion.

The repair of injuries, although with increasing age it becomes generally less ready and complete, is often very remarkable in even the oldest persons. This is especially true after injuries of the face and the upper half of the body; but in all parts and at any age healing may be expected unless hindered by local conditions, such as the impossibility of keeping parts in contact, as in fractures of the neck of the femur, or by conditions of general disease, such as would hinder healing at any age. Old persons appear, indeed, in less risk of the failure of local repair than of that general repair which should be achieved in convalescence. Some may have escaped all the immediate dangers of a severe injury or operation and all those of its earlier consequences, and the local injury may be nearly healed, but in what should be convalescence they waste, decay, and slowly die. This is especially likely to happen to those who are unable to take their usual food; and to those whose organs are not only degenerate through old age, but damaged by the effects of former diseases. Indeed, however striking may be the marked instances of repair of injuries in the aged, their risks from degenerate blood-vessels, weak hearts, habitual bronchitis, and other like defects, can never be deemed slight.

Among the sequences of injury, old persons are much less liable than the young to the infection of prevalent con-

tagions, such as scarlet fever and small-pox; less liable, also, to septic poisoning and pyæmia; rather more to erysipelas and to a more dangerous form of it with frequent relapses. Injuries, also, are very likely to bring out and localise the diseases to which old persons are liable; such as gout and osteo-arthritis, or the gangrene to which the diabetic are prone.

Inflammation in old age is usually less active than in earlier life; that is, under similar conditions and in the same parts, it is slower both in progress and in recovery; more likely to be or to become chronic; and, in cases which may be deemed of equal intensity, it is less productive of new organisable material, more prone to cedema, to mere congestion and gravitation of the blood, to more decay and sloughing of the softer tissues, or else to thickening and contraction which time does not repair. Commonly, too, inflammation in old persons shows less influence on adjacent lymph-glands than in the younger; they seldom become quickly or much swollen, still more seldom suppurate in a secondary inflammation. But the greater contrasts are due to the constitutional conditions which prevail in the different periods of life. Scrofula, which commonly gives its characters to the inflammatory process in early life, is in old age rare. Any scrofulous disease may, indeed, be found in even far advanced age, and all the characters of the scrofulous inflammation may be well marked in old persons who have never before shown signs of it; but this is as rare near the end of life as it is common near the beginning. The constitutions which more often put their mark on the inflammations in old age are the gouty and the so-called rheumatic gouty, such as appears in the changes of osteo-arthritis. These may be seen, indeed, in any period of life; but, even when they appear early or in middle age, they accumulate with advancing years, and are the cause of some of the most characteristic disabilities and infirmities of old age—the stiff curved spines, nodular and stiffened joints, contracted hands, deformed feet, and others. In all of these are evidences of thickened and contracted fibrous tissues, wasted articular cartilages, and nodular enlargements of the articular ends of bones, of which the type is seen in the justly named *malum coxæ senile*. And the effects of all these changes are the greater, because they coincide with the wasting and diminishing elasticity and

pliancy of tissues due to the natural senile degeneracies.

The progress of inflammation in old age is often affected by the accumulated changes of structure due to previous diseases in internal organs, especially those which hinder or weaken the movement of the blood, or materially alter its constitution. The persistency of eczema, and its tendency to ulceration in the lower limbs when the veins are varicose, is an example of the first, and the frequency of gangrene in senile diabetes is one of the second. There are also instances of peculiar nervous conditions in inflammation in old persons, such as the intense neuralgic pains which not only precede but often remain long after, the eruption in herpes zona, and in the pain of carbuncle and of senile gangrene, especially that which is associated with arterial degeneration.

In correspondence with the inactive and degenerative tendencies of inflammations in the old, they do not need, and often do not bear, active treatment. As a general rule, old people require more than ordinary care in securing rest and a good position for the inflamed part, warmth, sleep, a scarcely if at all diminished diet, comprising both vegetable and animal food, and, with moderation, any habitual quantity of stimulants. They commonly bear opiates well, especially when the inflammation tends to produce gangrene; but of other medicines it is generally true that, as age advances, so the utility of most things regarded as remedies in earlier life diminishes.

In comparing the pathology of Morbid Growths in old age and in earlier periods of life, it may be noticed that, although there may be no form of which the growth may not commence at any age, yet a very large majority of those commencing before the middle period of life are innocent tumours, and a very large majority after that time are malignant. In other words, the tumours which begin to grow in the earlier period are generally composed of structures like the fully organised and vascular tissues of the body; and those of the later period are generally composed of structures like the embryonic or the epithelial tissues. The contrast is marked enough to help in the diagnosis of tumours beginning in old age.

Among cysts, very few begin to form in old age. Sebaceous cysts sometimes do so on the scalp and on the trunk, but the more common event is, that they which have long existed, increase and ulcerate

through the thinned and feebly sustained skin. Seminal cysts, also, may first appear at an advanced age, and, even in the oldest men, they may be repeatedly filled with the characteristic fluid containing spermatozoa.

Fatty tumours, though rarely beginning, commonly continue to grow, in old age; and very often, with the progress of senile decay, the integument covering the most prominent or most dependent part of a fatty tumour sloughs or ulcerates, and may thus become dangerous to life. The chance of such an event may be counted among the reasons for removing such tumours in due time; for this chance is at least as great as that of the calcification of the tumour, in which its increase might be stayed. Many an old age is rendered unhappy by the weight and other troubles of a fatty tumour, which might have been removed safely many years before.

Among fibrous and myomatous tumours, those that are common in the prostate gland probably begin not rarely in old age, and those that have begun earlier may constantly increase. They are commonly a cause of the bossed and unsymmetrical shapes of enlarged prostate glands, and they are very rarely calcified. In this respect the uterine fibroid tumours differ from them; these not seldom in old age cease to grow, and become more dense and in parts calcareous. Of other fibrous tumours the growth may continue to the very end of life.

In cartilaginous tumours the decay of age is like to bring ossification; in osseous tumours increase. It is very rare to find instances of either kind beginning in old age, and in this there may seem strange contrast between the tumours and the very frequent and abundant osteophytes, which form, late in life, at the articular borders and other parts of bones.

Papillary tumours or overgrowths are commonly first formed in old age. They are exemplified in the warts on the scalps, and more rarely on the hands and feet of old people; in those of the tongue; and in the pigmental papillary growths on the back and other parts of the trunk; and in some of the 'bark-warts' on the face. Not a few of such papillary growths in the softer parts become in old age cancerous.

Nævi or erectile tumours, such as commonly begin in foetal life or earliest childhood, are in some degree imitated in old age, and in any time during or after middle life, by the little bright vascular spots which are commonly formed in the skin of

the trunk, especially in that of the front of the chest. But these never materially increase in size, or lead to grave disturbance, or need treatment.

The contrast between the whole group of the innocent and the malignant tumours, in respect to their first occurrence in the earlier or the later periods of life, has been already mentioned. A similar but not equal contrast may be observed between the two chief groups of the malignant, which are structurally distinguished as sarcomata and carcinomata, or as embryonic tissue and epithelial tissue tumours. The former may first appear at any time of life, and are more common in children and young persons than are many of the innocent tumours, such as the fatty and the fibrous. The latter are rare before middle age, but, after that time, their frequency in proportion to the number of persons surviving increases with advancing years.

Among the sarcomata, the myeloid, which, though structurally connected with the rest of the group, are clinically not malignant, are very rare in later life. So are the spindle-celled in an unmixed form; and these, also, are of the least malignant in that they very seldom recur at a distance from their primary seat, and very seldom infect the lymph-glands. Thus the less embryonic structures correspond with the less malignity.

The increasing frequency of cancer in advancing years is important in diagnosis. The older the patient the greater is the probability that a recently developed morbid growth is cancerous, or, at least, malignant. And it is true, not only of such as are produced in parts which previously appeared healthy, but of those which form in parts which were before harmlessly diseased. Thus, in advancing age, the crusted thickenings of skin called 'bark-warts' are apt to become seats of epithelial cancer; pigmental moles become malignantly melanotic. Similar changes not rarely occur in middle age; in the cancerous ulcerations of old scars, especially those of burns, and of the epithelial and papillary diseases of tongues; but, on the whole, the general rule seems true that the liability of many long-diseased parts to become cancerous increases with the increase of age. And another general rule, but subject to many exceptions, in the old is that the progress of cancers, both local and in their extension to lymphatics and distant parts, is slower than in the earlier times of life.

When cancer is transmitted by inheritance, it commonly appears earlier in those

to whom than in those by whom it is transmitted. The cancerous child may die before the cancerous parent; or a parent, who may have transmitted a tendency to cancer, may die before manifesting the disease in him- or herself.

The general characteristics of disease in old age are so especially illustrated in the diseases of some parts, that it is customary to class examples of them as distinct varieties. Thus, senile prurigo, senile purpura, and senile gangrene are often separately described, and may be studied as the best examples of disease modified by senile degeneration. They are treated of in their appropriate articles; and in several instances it is worth observing that the greatest frequencies of certain diseases are in old age and in early childhood. Thus it is with cataract, hydrocele, inguinal hernia, urinary calculus (at least among the children of the poor), phimosis, prolapse of the rectum, cutaneous warts, eczema, excess of uric acid, and some others. The causes of the similarly named disease at the two extremes of life may be in many respects widely different; the apparently similar result may be attained in dissimilar ways; but the fact may, nevertheless, deserve careful study.

ONYX.—A crescent-shaped, purulent infiltration at the lower part of the cornea, resembling the *lunula* of a finger-nail. It may be mistaken for hypopyon, and is indeed often associated with it. Unlike the latter, it does not change position with movements of the head. *See* HYPOPYON.

OÖPHORECTOMY.—This term is generally applied to the operation for the removal of an ovary or ovaries which, though diseased, are not so diseased as to form tumours of any size. It is also applied to the operation for the removal of

healthy ovaries, the object being in this case to bring on the menopause prematurely, and thus, by arresting the monthly nervous and vascular excitement in the uterine organs, to cure other diseases which are thought to be dependent upon these periodic disturbances, or are exacerbated by them. Its most successful and important application is in the removal of the ovaries and Fallopian tubes for the cure of fibromyoma of the uterus, and its indications and method of performance for this purpose will be found in the article on UTERINE TUMOURS.

It has also been advocated and practised for the cure of hystero-epilepsy and insanity, when these conditions appear to be associated with the catamenia. It is, however, very doubtful whether this is a legitimate field; the results at present obtained certainly do not encourage its frequent use in these cases.

There are two well-marked conditions of the ovaries, the result of blood-changes and inflammation, which may occasionally, if they can be correctly diagnosed, not only justify, but demand oöphorectomy. Their causes and pathology have been but little studied at present.

In the one case the ovaries are found enlarged, distended with unruptured follicles or small cysts, and with the outer coat much thickened. This condition is probably the result of chronic ovaritis, the thickening of the external layer of fibrous tissue preventing the rupture of the follicles. The affected ovary will usually prolapse from its weight, the prolapse still further interferes with its circulation, it is constantly congested, and is liable to injury during defæcation, sexual intercourse, or from the treatment of inexperienced gynaecologists. So long as it does not become adherent a cure is possible. The treatment should consist in a careful regulation of the bowels, avoidance or sparing use of sexual intercourse, rest in the recumbent position during menstruation, the thorough application of the continuous hot douche night and morning, and counter-irritants applied externally to the skin of the abdomen on the affected side. Sometimes a watch-spring ring pessary, if it can be worn, will aid the cure by supporting the ovary. Small and continuous doses of perchloride of mercury are also useful.

If one or both ovaries, thus diseased, become fixed by adhesions to the bottom of the pouch of Douglas, and especially if the uterus retrovert and press upon them, nothing but oöphorectomy will give relief,

and some of the most satisfactory results of this operation will be met with in this class of cases. It is, however, only justifiable when every other method of treatment has failed, and the patient has become a complete invalid.

In the other condition, referred to above, the ovaries on removal are found to be small, hard, and shrivelled—in fact, cirrhused—the follicles having entirely disappeared. This may be in some cases merely a further stage of the condition we have been considering, but there is good reason to suppose that it may result without such intermediate state, from the blood-changes in some of the specific fevers, notably scarlet fever and measles, especially when these diseases attack the patient severely about puberty.

With the large chronically inflamed ovary menstruation is generally irregular, but is more often too frequent and too free, while with the cirrhused ovaries it is painful, scanty, and with long intervals, or it may be altogether absent.

The cirrhused ovaries are rarely displaced, and can often not be defined by the most careful bi-manual examination. They are often bedded in adhesions to the Fallopian tubes, to the side of the broad ligament, or to neighbouring structures.

Nothing in the way of medicine or treatment seems to relieve the dysmenorrhœa or amenorrhœa in these cases, and though oöphorectomy may be occasionally successful, it does not seem to yield such good results as in the previous class. This is not to be wondered at, because the large ovary is, from its size and surroundings, and from the constant enlargement without rupture of the follicles, a source of constant pain, whereas the cirrhused ovaries are not so often painful in themselves, but are a cause of indirect suffering from the imperfect performance of their functions.

It will be found a good rule, and one that should rarely if ever be broken, to refuse to perform oöphorectomy unless an ovary can be distinctly made out, by physical examination, to be in a diseased condition. Even then the operation should never be performed, unless the surgeon is convinced that all other possible means of cure have had a fair and sufficiently prolonged trial. The only points in the method of performing the operation which need be alluded to, as Ovariectomy is given in full detail, are—

1. Greater care in opening the peritoneum.

2. Special care in sewing up the wound, as, the parietes not having been stretched,

a weak cicatrix, and the chance of ventral hernia, are more likely than after ovariectomy, unless all the layers of the abdominal wall are accurately united.

3. The greatest care should be taken to remove all the ovarian tissue and the tubes close up to the uterus; it is therefore necessary to leave a short stump, and the ligatures must be tied tightly. If both ovaries are removed, both pedicles should be transfixed and tied, and the sponging completed, before the organs are cut away.

The after-treatment is exactly the same as in ovariectomy. When both ovaries and tubes have been closely and cleanly removed, the patient usually has a short metrostaxis within a day or two after the operation, and then entirely ceases to menstruate, and loses her sexual feeling. The rare cases in which a third ovary is present, and escapes detection and removal, may account for some apparent exceptions to this rule. Other exceptions are due to imperfect removal of ovarian tissue: a very small portion left behind, even on the distal side of the ligatures, will not only keep up menstruation, but will leave the sexual appetite; indeed, in some cases, a small remnant of ovarian tissue thus left, and probably irritated by the neighbourhood of the ligatures, seems to increase the sexual feeling.

A very occasional metrostaxis will occur in young women after the most complete oöphorectomy, but there is always the chance of a third ovary in these cases. When the ovaries have been very adherent, so that they have to be literally scraped out, menstruation may continue for a time unaffected, and the same phenomenon is observed in some cases in which papillomatous ovarian growths have to be enucleated; evidently very small portions of ovarian tissue are sufficient to stimulate the uterus. In married women, the probable loss of sexual feeling should be clearly put before both husband and wife before the operation is performed.

Most patients suffer, for a longer or shorter period, after the operation from the usual troubles of change of life, such as chills, perspirations, flushings, headache, and pains in the joints.

OPHTHALMIA. See **CONJUNCTIVA**, Diseases of the.

OPHTHALMOSCOPY — the art of examining the interior of the eye with the ophthalmoscope. The optical conditions necessary for distinct vision are (1) transparency of the dioptric media of the eye

(cornea, aqueous humour, lens, vitreous humour); (2) accurate focussing, on the per-
 ceipient elements of the retina, of all rays
 passing through the pupil from the objects
 on which the attention is fixed. If the pupil
 remain widely dilated when a considerable
 amount of light is passing through it, we
 frequently see, and more especially when
 the eye is at the same time ametropic, or
 out of focus, that, instead of appearing black
 as usual, it is bright, and, as it were, shining
 with a yellow or yellowish-red light. When
 this is the case, we may observe that we
 are nearly in the line joining the source of
 light and the pupil. In other positions we
 see the pupil dark or black as usual. The
 ordinary black appearance is due to the
 fact that the head of the observer inter-
 cepts the rays, which would be reflected in
 the direction of his own eye.

The principle of the ophthalmoscope
 consists in bringing the eye of the ob-
 server in the axis of the cone of light which
 passes through the pupil of the eye ex-
 amined; when this can be done, it is evident
 that the conditions requisite for seeing the
 rays reflected from the interior of that eye
 are complied with. This was first done by
 Helmholtz, by reflecting light into the eye
 from the surface of a piece of glass, which
 being at the same time transparent, allowed
 some of the rays again reflected from the
 interior of the eye to pass into the observer's
 eye placed behind the glass, and by means
 of these transmitted rays the fundus became
 visible. A modification was soon intro-
 duced, by which the image obtained became
 more luminous and distinct. This consisted
 in making use of a metallic or silvered glass
 mirror, with a hole in the centre. The eye
 of the observer, placed at the back of the
 mirror close up to the hole, enables him to
 catch some of the rays reflected from the
 fundus of the eye into which the light has
 been thrown by the mirror, and in this way
 to obtain the desired image. This arrange-
 ment is that of the *ophthalmoscope mirror*
 as it is now used. Various forms are given
 to the mirror; thus it may be plain, con-
 cave, or convex, or the two surfaces of the
 silvered glass may have different curvatures,
 and these be again either homocentric or
 heterocentric; but the main points, so far
 as the mirror is concerned, are that there
 shall not be disturbing reflections from
 the two surfaces or from the sides of the
 aperture, both of which conditions are com-
 plied with by making the glass thin or by
 using polished metal.

Two methods of ophthalmoscopic ex-
 amination are in use—the *indirect* and the

direct, both of which have their advan-
 tages. (1) In the indirect examination,
 the ophthalmoscope, placed close to the
 observer's eye, is held at from 12 to 20
 or more inches from the eye to be ex-
 amined, at a few inches from which and in
 the line of the rays reflected from the eye,
 the observer holds a convex lens of $2\frac{1}{2}$ - to
 3-inch focus. When the mirror is so placed
 as to cast the light into the eye an inverted
 aerial image of a portion of the fundus
 oculi is found between it and the convex
 lens, and situated at or near the focus of the
 latter (according to the state of refraction of
 the eye). It is this image which forms the
 actual object of examination. In order that
 this aerial image may be seen distinctly, it
 is evident that the observer's eye, and with
 it of course the ophthalmoscope mirror, must
 at least be as far from it as the distance of
 the observer's near point.

(2) By the direct method a much
 greater magnifying power is obtained, but
 a smaller portion of the fundus is seen
 at one time, so that, for a topographical
 examination and for making a quick sur-
 vey of the back of the eye, the indirect is
 more satisfactory; indeed, it is but seldom
 that the use of the direct examination
 affords information of diagnostic importance
 which would escape detection by the more
 rapid indirect method. In examining by
 the direct method, the observer brings his
 own eye and mirror close up to the eye
 to be examined, in which case, if his own
 refraction be normal (emmetropic), he will
 receive on his retina an image of the fun-
 dus from all eyes the rays from any point
 of the back of which are parallel, or moder-
 ately divergent, on emergence—that is to
 say, from emmetropic, or not too highly hy-
 permetropic, eyes. To see the fundus dis-
 tinctly in cases of myopia, it will be neces-
 sary for him to place in front of the eye he is
 examining—or, more conveniently, imme-
 diately behind the aperture in the mirror of
 the ophthalmoscope, a concave lens suffi-
 ciently strong to convert the rays, which
 from points in the myopic fundus are con-
 vergent on emergence, into parallel or moder-
 ately divergent bundles. It is evident,
 then, that an ophthalmoscope to be used
 for direct examination is necessarily a little
 more complicated than that which will
 suffice for indirect examination, inasmuch
 as it requires the addition of lenses be-
 hind, or at any rate some arrangement
 by which lenses can be placed behind the
 aperture in the centre of the mirror. As
 ordinarily manufactured, it is fitted with
 a number of lenses, which can be brought

into position by some simple mechanical arrangement, and which enables the observer, on the assumption that both he and his patient are fully relaxing their accommodation, to ascertain the state of refraction of the eye he is examining.

A number of different forms of ophthalmoscope, with lenses capable of being moved into position behind the centre of the mirror—so-called 'refraction ophthalmoscopes'—are in use. Some of these are more fanciful and of less practical value than their inventors believe. The chief points to which attention should be given in selecting such ophthalmoscopes, besides those already mentioned, are that the mirror should be capable of being inclined to 30° , or thereabouts, to either side; that the aperture should not be very small, and should be placed as near as possible to the lens behind it; and that there should be a sufficient number of lenses of not greater than 1 D interval between each. With a properly constructed ophthalmoscope and considerable practice, a fair degree of approximation can be made to the degree of ametropia by the direct examination, provided always that the ametropia is not excessive.

The points to which special attention should be given in making an ophthalmoscopic examination are the following:—1. The degree of transparency of the dioptric media; 2. the condition of the optic nerve and vessels; 3. the condition of the fundus at and around the macula lutea and, 4. at the periphery.

The degree of transparency of the media is made out mostly by means of the mirror alone. The reddish reflex from the back of the eye obtained by throwing light into it, reveals, by its greater or less uniformity and clearness, whether or not any obscurity exists in any of the dioptric media. Sometimes, when slight and diffuse, an opacity may only first be recognised when an attempt is made by either method of examination to obtain an image of the fundus. Under such circumstances, the details of the structures otherwise visible at the back of the eye appear veiled, so that they are more or less indistinctly recognisable. Opacities, made out by using the mirror alone, may completely interrupt the reflex from the fundus, or do so only partially, here and there, and may be stationary, altering their position only with the eye, or movable ('floating opacities'). The complete opacities are mostly due to dense exudations in the vitreous, either inflammatory or hæmorrhagic, inflammatory exudations occluding the pupil, and advanced cataract. Extensive

exudations or effusions of blood into the anterior chamber are readily diagnosed by other means than ophthalmoscopic examination. *Partial* opacities, again, when not in the cornea or aqueous chamber, are to be found in the lens and vitreous. In the lens they are, practically, invariably stationary, and can be localised from the direction in which they alter their position with movements of the eyeball. As the lens lies anterior to the point of rotation of the eyeball, the change in position coincides in direction with that of the eye, and is more extensive the more anteriorly the opacity is situated. Opacities of the lens appear with the ophthalmoscope in various shapes as dark striæ, dots, or diffuse patches, according to the nature of the lenticular change. So, also, the track of a foreign body which has passed into the eye through the lens is easily detected, by the more or less dark area of interruption in the reflex.

Opacities of the vitreous are either stationary or floating, and assume many varieties of shape, density, and colouring, according to their origin and nature. If stationary, they alter their position in a direction opposite to that of the eye, unless when far forward, as in the case of the plastic exudations immediately behind the lens in some cases of inflammation of the ciliary body (cyclitis). Vitreous opacities appear punctiform, filiform, membranous, or in large irregular dark patches, which latter are often blood-clots, and not infrequently give a dark reddish reflexion. The colour of a large mass of blood, as well as of a growth in the vitreous chamber, is often more distinctly seen by placing the ophthalmoscope mirror at the side of the eye, instead of straight in front of it. Occasionally, in old-standing disease of the eye, the opacities in the vitreous are seen to sparkle with a metallic lustre, owing to the development of cholesterine in the particles of exudation (*synchysis scintillans*).

In examining the optic nerve, attention must be paid to the following points:—(1) Its colour, transparency, contour, and surface. (2) The size and condition of the arteries and veins. (3) The appearance of the structures immediately surrounding it.

1. The intraocular end of the optic nerve, the *papilla optica* or *optic disc*, is normally transparent, its fibres being divested of their opaque myeline sheaths in passing through the sclerotic coat, altered in this position to a fine close network of connective tissue—the *lamina cribrosa*. As the depth of the transparent portion of the papilla is greatest in the nasal half, that portion is

more highly coloured and less different from the adjacent retina than the other parts, especially the outer portion of the temporal half, all of which is paler than the nasal half. The colour of the nerve as a whole, as well as of its different portions, is subject to very considerable physiological variation. Mistakes are frequently made by not keeping this in mind. Pathologically, the colouring of that portion of the optic nerve which can be seen with the ophthalmoscope may be increased or diminished. It is increased owing either to increased vascularity or swelling, as in hyperæmia and optic neuritis. It is diminished owing either to diminished vascularity or to shrinking, displacement, or loss of substance, as in anæmia, optic atrophy, and glaucoma. The excessive pallor which it assumes in cases of atrophy is greatly owing to the strong white of the lamina cribrosa shining through. It must be remembered that, owing to the great amount of white light reflected from the lamina cribrosa, the colour of the nerve, as seen with the ophthalmoscope, depends a good deal upon the amount of light thrown into the eye; the stronger the light the paler does the nerve appear. Occasionally, masses of pigment, seldom extensive, are to be seen in the papilla as a physiological variety; they lie in the deeper layers of the nerve on a level with the choroid, so that the retinal vessels may be seen to pass over them from the nerve. In health, the margins of the nerve are sharply distinguishable from the surrounding tissues. This distinct outline is lost more or less completely in cases of neuritis, owing to the swelling and hyperæmia of the nerve, sometimes, indeed, so entirely that the actual position of the nerve itself is mainly recognisable from the position of emergence of the great vessels, or, when that point is obscured by the swelling, by the situation from which they appear to diverge. In rare cases, some of the optic nerve-fibres retain their myeline sheath for some distance into the nerve-layer of the retina. This condition also gives rise to the ophthalmoscopic appearance of an obliteration of the sharp margins of the papilla, but is easily recognisable from that caused by neuritis.

The surface of the nerve again is subject to varieties both in health and disease. As already mentioned, the outer portion is not so deep as the nasal, and it not infrequently happens that there is a funnel-shaped depression in the centre, or slightly to the temporal side of the centre, of the nerve. The extent of this depression, both in

depth and superficies, is very variable. It has received the name of 'physiological excavation of the papilla.' The ophthalmoscopic appearance of such a physiological excavation is that of a white disc, the absence of colour in which contrasts strongly with the other parts of the nerve, especially the portion lying to the inner or nasal side of the depression. Within this disc the vessels appear out of focus, but by selecting the proper lenses to place behind the ophthalmoscope mirror in the direct examination, they may be traced down to the bottom of the depression, converging to the point from which they bifurcate, and following exactly the walls of the funnel-shaped depression. On focussing accurately the bottom of the depression, the meshes of the lamina cribrosa are often distinctly visible. If the examination be made by the indirect method, and the convex lens be moved from side to side, the peripheral ring-shaped portion of the nerve appears to glide more or less distinctly backwards and forwards over the indistinctly visible vessels of the central disc, a parallax movement which shows that the latter are out of focus, owing to their lying at a deeper level than the rest of the surface of the nerve. Excavation of the optic nerve occurs also pathologically in glaucoma and optic atrophy. When it occurs in glaucoma, the whole cross section of the nerve gradually recedes, owing to the increased intra-ocular tension; the vessels are observed to bend sharply round the edge of the nerve, and to be pushed towards the inner side, the surface of the nerve appearing at the same time of a bluish-white colour, and giving the characteristic parallax, on indirect ophthalmoscopic examination, indicative of a depression. The vessels can not generally be traced down the side of the depression, but appear discontinuous from the edge to the bottom of the excavation, where, as the atrophy of the fibres caused by the pressure increases, the retiform structure of the lamina cribrosa becomes more and more distinctly visible. Excavations, in cases of optic atrophy, are less characteristic, though seldom likely to be confounded with true glaucomatous changes.

2. The central artery and vein branch, at various depths in the nerve, into two main trunks, which pass upwards and downwards, afterwards subdividing somewhat, and curving outwards round the region of the macula. The arteries are somewhat narrower and for the most part straighter than the veins, and appear with the ophthalmoscope lighter in colour, owing to the

difference in the colour of the blood and greater thickness of their walls. This latter circumstance gives rise also to a reflection seen as a white stripe along the arteries, and only very indistinctly marked in the case of the veins. The arrangement of the vessels is subject to physiological variation, and not infrequently there is to be seen a more or less distinct pulsation in one or more of the venous trunks lying in the papilla. Pathological changes are met with in the vessels, with respect to their position, size, configuration, and blood-current. As already stated, the pressure which leads to pathological excavation of the papilla, often causes a displacement of the vessels, pushing them more or less completely to the inner side. Both arteries and veins, or more frequently the arteries alone, may be much diminished in size in various atrophic processes, as in retinitis pigmentosa or other secondary and primary optic atrophies, sometimes so completely as to give rise to the appearance of mere threads. In neuritis optica the vessels, more especially the veins, are greatly swollen and tortuous, their perivascular spaces sometimes being loaded, and appearing as parallel whitish lines on either side. Aneurismal dilatation, as well as hæmorrhage around the vessels, is also met with as the result of pathological processes. A not very uncommon occurrence is a rhythmic pulsation in either the venous or arterial trunks. Venous pulsation is not generally pathological; but, when occurring over a large extent of the vessels, is due, most frequently, probably, to Graves's disease, or insufficiency of the tricuspid valve. Arterial pulsation is usually due to increased intraocular tension, and is therefore a frequent symptom in glaucoma, where it is almost invariably confined to the trunks or the papilla; a more extensive arterial pulsation is sometimes seen in Graves's disease, and along with aortic regurgitation. Three conditions—embolism of the central artery, thrombosis of the central vein, and hæmorrhage into the sheath of the optic nerve, produced by fracture through the foramen, cause a varying degree of interruption in the current through the retinal arteries and veins, which may often be distinctly recognised with the ophthalmoscope.

3. Immediately surrounding the disc there is usually seen a narrow white zone, the so-called scleral ring, the portion of the sclerotic immediately surrounding the nerve being seen, owing to the aperture in the choroid being larger than that in the sclero-

tic. Immediately surrounding the scleral ring, again, may be seen a ring of choroidal pigment, or, much more commonly, only a crescentic, or it may be one or more crescentic portions of such a ring, more often on the temporal side, where the choroid seldom lies so close up to the nerve as elsewhere. It frequently happens that the breadth of the scleral ring in this position is pretty considerable, owing to the same cause, and this occurs as a physiological variation independent of the state of refraction; but, when more than about one-third of the papilla in breadth, it is usually associated with some change or atrophy of the corresponding part of the choroid, and is most generally found in myopia, constituting the change which has received the name of *staphyloma posticum*, the importance of which has been greatly exaggerated. In high degrees of myopia the staphyloma posticum is seen to extend right round the nerve, though almost always most extensive at the temporal side. In glaucomatous excavation of the papilla the scleral ring disappears, the excavated nerve being surrounded by a more or less broad yellow ring, due to some degenerative change in the choroid.

In health the retina is transparent, so that the only structures which are visible in it are the vessels, which are to be seen dividing dichotomously all over except at the centre or region of the macula lutea, where there is a conspicuous absence of large vessels, the region being mainly supplied by fine twigs curving outwards from the papilla above and below it. These all converge towards the macula, without, however, being traceable right up to it. The distinctness with which the deeper structures of the choroid is to be made out depends upon the density of the pigment in the hexagonal cells, histogenetically belonging to the retina, but more strongly adherent to the choroid. When this pigment is very dense, it completely excludes any view of the choroid; otherwise a more or less distinct picture is obtained of the vascular system of that membrane, according as its own cells are more or less filled with pigment. With little pigment in the hexagonal cells and much in the choroid, only the larger choroidal vessels are visible, the variously shaped interspaces between which are darkly pigmented. With little pigment in both retina and choroid, the whole capillary system of the latter (choriocapillaris) is also recognisable. There is, therefore, a great difference possible in this respect in the ophthalmoscopic appear-

ance of the fundus in different individuals, the two extremes being met with in the negro and albino.

The retina is subject to various pathological changes, either as a whole or in its vessels and pigment-cells, the alterations being for the most part accompanied by changes in the choroid and nerve. A loss of transparency occurs whenever there has been a sudden disturbance in the retinal circulation, brought about by one of the causes already mentioned, the retina assuming an opaque, whitish appearance, due to œdema. This change takes place over a greater or less extent of the membrane, but is absent in the macula, owing to the retina in that situation being thinner, so that the normal red reflection is preserved there, giving the appearance, on ophthalmoscopic examination, of a bright red spot. The transparency of the retina is also more or less altered by inflammation (retinitis), when it at the same time becomes hyperæmic, and in some situations distinctly striated, owing to swelling of the layer of nerve-fibres. Detachment of the retina, if it has existed for some time, causes it to lose its transparency and to assume a greenish or bluish-white aspect. When recent, detachment of the retina is not always very easy to diagnose, owing to œdema of the undetached portion, the frequent cloudiness of the vitreous, and the retention of its transparency by the portion detached. When the pushing forward of a detached portion is at all considerable, it can generally be seen to lie out of focus, requiring a different glass behind the ophthalmoscope from that with which other parts are seen distinctly, to bring it prominently into view; thus the vessel becomes indistinct at the edge of the detached membrane, and can again be seen distinctly only by accurate focussing; in this way it is possible to diagnose the abnormal position. *See* VITREOUS, Diseases of the; RETINA, Affections of the. Different sized hemorrhages of various shapes are to be seen in the retina in certain affections of the blood, as in leucocythæmia and pernicious anæmia, or owing to inflammatory and degenerative changes in the vessels. The small extravasations are mostly flammiform, but larger ones assume all sorts of irregular shapes.

From what has already been said, it will be readily understood that choroidal affections often do not produce changes recognisable with the ophthalmoscope, unless they have, either from the first or subsequently, been of such a nature as to involve

the retinal pigment; thus, we may have an acute choroiditis existing, with little other ophthalmoscopic change than the opacity of the vitreous caused by part of the exudation having found its way into the vitreous chamber. As soon, however, as the hexagonal cells are invaded, the masses of exudation and degenerative changes which exist at the sites of inflammation come into view, giving rise to very different appearances. The exudations into the choroid may take place in large diffuse patches, producing the appearance of yellowish or white plaques, bordered in places, and here and there covered by masses of displaced and proliferated pigment, or they may occur in disseminated small patches of various shapes, and at different parts of the fundus. Often such changes first make their appearance at the equator, for which reason, as already observed, it is important to make careful examination of the peripheral portions of the fundus. Cases in which the retinal pigment is scarce, whilst the cells in the choroid are densely pigmented, give rise to such a curious mottled appearance that one is apt to consider the condition pathological. This is, however, only justifiable when different portions of the fundus present widely different appearances in this respect, or when, though little or no view of the choroid is obtained in some situations, it is distinctly visible in one or more localities; we may then assume that there has been some process leading to change or atrophy in the hexagonal cells, an assumption which can often be verified by proper subjective tests.

Choroidal changes are often limited to the region of the macula, especially in old people, so that an examination of that region should always be made when an amblyopic defect is unaccounted for by appearances elsewhere. It is often very difficult to get a distinct view of the centre of the retina, owing to the fact that the concentration of light on the macula causes great contraction of the pupil, besides which, the reflection from the cornea frequently adds to the difficulty. It is, therefore, necessary to use some mydriatic, the most convenient for such purposes being homatropine. In the form of retinal sclerosis or inflammation which has received the name of retinitis pigmentosa, there are generally to be seen, besides atrophic changes in the nerve and vessels, a number of bone-corpuse-shaped pigmentary spots, which may easily be made out to lie well into the retina. Their appearance is very characteristic, and is most frequently met with

in a ring-shaped distribution between the centre and equator.

With the exception of the scleral ring, to which reference has been made above, no portion of the sclerotic is visible with the ophthalmoscope in a healthy eye. A beautiful ophthalmoscopic appearance is given by a somewhat rare congenital defect, which consists in the partial absence of the choroid. In this condition of coloboma of the choroid the sclerotic is brought into view lying as a bright white membrane below the transparent retina, the vessels of which may be seen crossing it at various places. A defect of the choroid allowing the sclerotic to come into view is also met with as the result of accident—rupture of the choroid. The ophthalmoscopic appearances of this accident are at first frequently so veiled by the hæmorrhage accompanying it, and which destroys for the time being the transparency of the vitreous humour, that it is generally not until some time that a distinct view is obtained. The rupture generally takes place at the back of the choroid, in the vicinity of the nerve and macula.

OPISTHOTONOS. *See* TETANUS.

OPTIC NERVE, Diseases and Injuries of the.—**CONGENITAL ABNORMALITIES.**—A. Not infrequently there is a very delicate veil of connective tissue over the central blood-vessels at their exit, and for a short distance beyond. Sometimes this condition is much exaggerated, rendering the disc decidedly pale, and obscuring the vessels.

B. Imperfect closure of the embryonic fissure in the optic cup and adjacent part of the pedicle leads to coloboma of the iris, choroid, or optic nerve-sheath, according to the part involved. The latter—coloboma of the sheath of the optic nerve—is comparatively rare. The main branches of the central vessels are seen to emerge near the upper edge of the disc-area, while the lower part, corresponding to the cleft in the sheath, is very pale and deeply excavated, with fine vessels curving round its margins. The appearances vary considerably in different cases, and the condition is frequently accompanied by coloboma of the neighbouring part of the choroid below.

DISEASES.—The optic nerve, with its retinal expansion, is a direct prolongation of the brain, and it will be well to bear in mind this relationship as serving, in some measure, to explain their peculiar liability to suffer in intracranial disorders. For the ophthalmoscopic appearances of the normal

optic disc and its variations, *see* OPHTHALMOSCOPY.

Pathology.—This nerve is peculiarly prone to suffer in affections of the central nervous system, in some forms of chronic poisoning, and in certain general disorders. Inflammation of an acute or chronic character may attack it at any point in its course, may affect its whole thickness or only a part of it, and may or may not lead to permanent atrophy, total or partial. Again, without recognised inflammation, the nerve may undergo degenerative changes resulting in a simple atrophy. Occasionally, the occurrence of an inflammation or simple atrophy of the nerve is intelligible enough, as, e.g., an optic neuritis in association with orbital cellulitis, or a simple atrophy subsequent to rupture of the nerve-trunk. Generally, however, the pathological process is most difficult to trace, and our knowledge must still rest largely on hypothesis. It is impossible, in the space at our disposal, to enter into discussions as to the relation between optic neuritis and intracranial disease, &c.; but the following facts should be remembered in connection with the exceptional vulnerability of this nerve.

1. From its development and structure the optic nerve is to be regarded as a direct prolongation of the central nervous system, and is therefore to be distinguished from ordinary cerebro-spinal nerves.

2. Their position and long course along the base of the brain render the nerves, commissure, and tracts liable to be affected in inflammation of the membranes in this locality and in cases of intraventricular pressure.

3. The sheaths of the nerve are derived from the membranes of the brain, the outer having also a connection with the periosteum lining the orbital canal. These sheaths are in close relation with one another by means of numerous connective-tissue processes throughout their course, and the innermost sheath enters intimately into the structure of the optic nerve, besides sending a special, large process to accompany the central blood-vessels, and run in the axis of the nerve. Ultimately, the sheaths join the coats of the eyeball at the optic nerve-entrance, where they are associated with the fibrous processes forming the lamina cribrosa. We thus have the possibility of a direct transmission of an inflammation, of the meninges or of the orbital periosteum, along the sheaths to the fibrous framework of the nerve itself; which latter may be attacked at the lamina cribrosa, at the en-

trance of the blood-vessels, at the optic foramen, or along its course in the orbit.

4. The inter-vaginal spaces of the nerve are in connection more or less intimate—(a) With the meningeal cavities of the brain; (b) with one another; (c) with the lymphatic spaces around the nerve-fibre bundles; (d) with the lymph-channels of the surrounding orbital tissue. The fluid circulating in the lymphatic system of the nerve may therefore contain inflammatory material, primarily derived from within the cranium, or possibly from the orbital tissue, and thus an inflammation may be communicated to the nerve framework. Again, serous fluid or blood effused in the meningeal cavities may find its way into the sheath-spaces, and injure the nerve by direct pressure.

5. The absence of a primitive sheath possibly renders the nerve-fibres more vulnerable in the post-bulbar portions, while, in the intra-ocular portion of the nerve, the naked axis-cylinders are directly exposed to the action of the lymph.

6. The narrowness of the optic foramen is liable to cause further constriction in an already existent œdema, while, in like manner, the disposition of the lamina cribrosa tends to promote a similar effect by its pressure on the blood-vessels and lymphatics. Finally, it must be borne in mind that we can detect inflammatory and atrophic changes in this nerve, which might readily escape notice in other cranial nerves.

1. INFLAMMATION OF THE OPTIC NERVE.

Pathology.—The optic disc or papilla, or intraocular end of the nerve, is the part commonly affected; and then the inflammation generally stops abruptly at the lamina cribrosa, but may exceptionally extend a short way beyond this structure as an 'ascending neuritis.' In other cases, an inflammation, beginning in the nerve-trunk, may travel downwards and involve the papilla secondarily, constituting what is called a 'descending neuritis.' 'Papillitis' is a useful term for the condition in which the papilla is involved, the expression 'optic neuritis' being retained as the generic term for inflammation of any part of the nerve. When the inflammation attacks the nerve-trunk behind the eyeball, we speak of it as a 'post-bulbar neuritis.' In many such cases no papillitis is ever manifest. All forms of neuritis are probably interstitial in nature, yet the early stage of a severe papillitis is unaccompanied by affection of the connective-tissue, the changes merely consisting of venous

hyperæmia, œdematous infiltration, and hypertrophy of the axis-cylinders. If the inflammatory process stop short at this stage, and recovery take place, we may ultimately get a healthy disc and retention of normal vision.

In an interstitial inflammation we have, at first, cellular infiltration and swelling of the vascular connective-tissue framework, and, subsequently, hypertrophy of this structure; so that the nerve-fibre bundles become reduced in size from pressure, and either finally disappear or undergo grey degeneration (post-papillitic atrophy). In the later stage of a papillitis, the walls of the blood-vessels are thickened, the adventitia being increased, and the middle coat of the arteries often considerably sclerosed. The surrounding retina is frequently affected for some distance, changes of a similar nature to those in the papilla occurring in the nerve-fibre layer (papillo-retinitis). As previously observed, optic neuritis does not necessarily affect the nerve in its entire thickness. In some cases the periphery is mainly involved, and we have the condition known as 'perineuritis.' In other cases, the inflammation is limited to the central part of the nerve affecting the fibres going to the fovea centralis and neighbourhood, as in the variety called 'axial neuritis.' As a rule both nerves are affected, and similarly, though not necessarily to the same degree, nor at the same time. Unilateral optic neuritis is generally dependent on a local cause, such as orbital cellulitis; but it may also occur in association with intracranial tumour, &c.

Ophthalmoscopic Appearances.—We must be extremely cautious in diagnosing positively the slightest departures from the normal vascularity of the papilla, since its colour varies considerably in health in different individuals, and it is also subject to temporary hyperæmia from vasomotor influences. It is always desirable to employ the direct method of ophthalmoscopic examination (*see* OPHTHALMOSCOPY); but especially so when the apparent changes are insignificant; and we must invariably examine both eyes. The condition called 'active hyperæmia' is recognised by a slightly increased, general vascularity of the papilla, its tint being of a more pronounced red than is normal, but the relative size of arteries and veins remaining unaltered. The edge of the disc may be less sharp than usual; but it is not obscured, and there is no swelling. We find it as a result of prolonged exertion of the eyes by

artificial light, also in muscular or accommodative asthenopia, and from the irritation of foreign bodies, &c. In 'passive congestion' of the papilla we not only have increased redness, but also dilatation of the veins, the arteries being of normal size or slightly diminished. Between a simple congestion, with the characters just mentioned, and a fully-developed papillitis or 'choked disc' there are many gradations, marked by more or less swelling, blurring of the edges, and obscuration of the larger vessels. These gradations may simply be stages in the development of a high degree of papillitis, or any one of them may be the final condition where the affection of the papilla is of less severity.

In advanced papillitis the appearances are the following:—The edge of the disc is obscured and, while its general vascularity is greatly increased, there is a loss of translucency, with a greyish haze dulling the usual bright reflex. The whole papilla is distinctly swollen above the level of the adjoining retina, and the physiological cup is obliterated. Numerous straight vessels radiate from it on every side, coursing over its obscured edge. The larger vessels, especially the arteries, are frequently hidden at their origin on the papilla, and again in their course over it or just outside it. Frequently, small hæmorrhages occur either on or in the vicinity of the disc. Smooth, opaque, white spots occur on the disc or on the surface of the adjoining retina, concealing completely what they cover. The veins are enlarged, dark and tortuous, and the normal light-streak is absent. The arteries are usually somewhat narrowed. The retina, especially near the disc, is frequently cloudy over smaller or larger areas. The swelling of the papilla and the obscuration of its margin are to be explained by the action of several distinct factors—viz. vascular congestion, œdema, changes in the connective-tissue (swelling and proliferation of nuclei), escape of leucocytes, and degenerative changes in the nerve-fibres, accompanied by swelling and irregular enlargements. The striation near the margin of the disc is due to the presence of dilated vessels, running between the swollen nerve-fibres. The increased vascularity is at first inflammatory, but, later, it is partly owing to secondary interference with venous return; this latter is also the cause of the enlargement and tortuosity of the veins, and of the occurrence of the hæmorrhages. The opaque white spots are due to fatty degeneration of the nerve-fibres, and to aggregations of leucocytes.

As the papillitis diminishes, we find the redness of the papilla disappearing, while the swelling becomes reduced both in height and extent. The veins may, for a time, be more distended than before, but generally all the vessels are ultimately much narrowed. The edge of the disc again becomes distinct, the outer margin coming first into view. Around it there is frequently a pale zone, the result of changes in the retinal pigment. The disc itself is opaque and woolly-looking at first, but it gradually becomes smoother; its surface is occupied by newly-formed fibrous tissue which conceals the lamina cribrosa. In the stage of atrophy, the disc is usually of a brilliantly white colour, and the larger vessels are frequently bordered by opaque white lines. In cases of post-bulbar neuritis, the resulting atrophy is frequently the first ophthalmoscopic sign of the disease, but occasionally we have simple passive congestion or even considerable papillitis preceding the atrophic condition.

Symptoms.—Not only do we usually have no ocular pain or photophobia, but there may not even be any complaint of loss of vision. Indications of intracranial disease often lead us to examine the eyes, and thus to discover well-developed ophthalmoscopic signs of neuritis, in cases where there have been no local symptoms. Vision may remain perfectly good for some time; indeed, in exceptional cases, papillitis may occur and disappear again without its ever being impaired. Usually, however, loss of sight is a prominent symptom. It sometimes occurs rapidly, but never suddenly, and one eye is generally attacked a little before the other. If amblyopia occur quickly in an early stage of the papillitis, it is usually not due to the inflammation, but to pressure of a tumour or distended third ventricle on the chiasma or optic nerve. The form of the amblyopia varies according to the kind of the neuritis. In that due to an ordinary papillitis we have a gradual failure of central vision, with progressive diminution of the visual field from the periphery. The contraction usually begins on the nasal side, extends gradually all round, and, after the fixation point has been invaded, we may still have a small eccentric outer field. The colour vision in such a case may be lost out of proportion to the amblyopia, but the kind of failure is very irregular. In many cases of post-bulbar neuritis—in the axial form for example—we have the amblyopia first appearing as an impairment of central vision, while the periphery of the field re-

mains perfect. The loss of colour vision is here characteristic; the power of distinguishing red and green in a small central area being often lost in the very beginning of the affection. In some of the post-bulbar cases there is deep-seated pain in the orbit, excited or aggravated by pressing the eyeball backwards.

Causes.—Intracranial disease is by far the most common cause of papillitis. All tumours of the encephalon, irrespective of their nature, position, or size, are apt to produce it; but it is relatively rarer in tumours affecting the cortical motor area and the medulla, and most frequent in those of the cerebellum and base. We also find it in association with meningitis (especially traumatic and tubercular basilar), with cerebral abscess, and sometimes with chronic cerebritis without gross lesion. Injuries to the head may cause optic neuritis either through meningitis, effusion of blood (within the skull or within the nerve-sheath), hernia cerebri, or possibly through a laceration of the brain. It occasionally accompanies internal hydrocephalus, or aneurism of the internal carotid artery within the skull. In many orbital affections we are liable to get optic neuritis: (*a*) in orbital tumours, especially when situated in the immediate vicinity of the nerve; (*b*) in intraorbital inflammation, such as periostitis and caries of the walls, orbital cellulitis and erysipelas, whether traumatic or idiopathic; (*c*) in congenital malformation and hyperostosis of the skull, from narrowing of the optic foramina. In (*a*) there is usually protrusion of the eyeball; in (*b*) the papillitis is seldom of high degree; in both (*a*) and (*b*) the neuritis is nearly always one-sided. Papillitis has also been observed in association with acute myelitis, and in cases of injury to and caries of the spine in the cervical region.

Occasionally, we get papillitis occurring alone in cases of Bright's disease, but usually we have here a peculiar form of retinitis in combination with it. In chlorosis, and in progressive pernicious anæmia, we may meet with papillitis or papillo-retinitis, and also, more rarely, in leucocythæmia. In the anæmia following repeated large losses of blood, for example in hæmatemesis, papillitis has been described, but more commonly we get post-bulbar neuritis in such a condition. In these latter cases, the neuritis has been ascribed to the hydræmia, which according to Cohnheim may in itself excite inflammation in the vascular walls. Papillitis occasionally occurs in association with menstrual disturbances, such as sudden suppression or

habitual irregularities, and at the climacteric period. Acquired syphilis may be the cause of optic neuritis, either through meningitis or a gummatous growth, the latter being situated either within the skull, at the optic foramen, or on the nerve-trunk; the neuritis is mainly post-bulbar, and generally one-sided when the gumma is in one of the last two situations. A temporary 'hyperæmia' of the papilla has also been described as occurring in a considerable percentage of cases of syphilis during the secondary stage, attributed to a 'cerebral irritation or hyperæmia.'

In diabetes mellitus we get an axial neuritis, and, from the similarity of the symptoms in chronic poisoning by lead, alcohol, tobacco, and bisulphide of carbon, a similar affection of the optic nerve probably also exists in these latter affections. In the more acute cases of poisoning by these agents, slight papillitis or simple congestion of the papilla may be observed. Papillitis or post-bulbar neuritis sometimes occurs in patients suffering from acute exanthematous diseases (typhus fever, scarlatina, variola) and from malarial fevers. An acute post-bulbar neuritis or papillitis without definite known cause is occasionally met with. A certain number of such cases has been ascribed to a rheumatic periostitis at the optic foramen or to rheumatic inflammation of the nerve-sheath, in as far as there is a history of the arthritic diathesis, and often of a chill preceding the ocular symptoms. Other obscure cases seem due to an hereditary predisposition, and occur usually about the age of twenty, and almost exclusively in males. Optic neuritis is sometimes merely caused by an extension of an inflammation from a neighbouring tissue in the eyeball, and it has also been observed in an early stage of sympathetic inflammation, before the occurrence of iritis.

The *prognosis* in all cases of optic neuritis must be guarded, in reference to the final condition of the vision. The ophthalmoscopic appearances presented are of less service to us, in this respect, than a knowledge of the cause of the disease. We may have a papillitis with good vision leading ultimately to complete atrophy and blindness; while again, we may have a papillitis with the barest perception of light (as in occasional post-bulbar cases), followed by almost perfect recovery of sight. The prognosis is relatively more favourable where the cause is removable or amenable to remedies; thus, cases dependent on syphilis, menstrual disturbances, or anæmia may

recover without serious permanent changes under early suitable treatment. Similarly, an axial neuritis from chronic poisoning by tobacco, alcohol, &c., is speedily checked by removal of the cause; but the impairment of vision may remain, if atrophy of the affected fibres has already taken place.

Treatment.—The cause of the neuritis must if possible be removed, or attacked by the remedies most likely to prove serviceable. Where not contra-indicated or manifestly useless, mercury and iodide of potassium should be employed as a matter of routine, the latter being given in full doses. Rest in its widest acceptance is to be insisted upon. The direct treatment of the neuritis itself is unsatisfactory. Dry or wet cupping by means of Heurteloup's artificial leech to the temple, and blisters to this region or behind the ear may be tried. The application of ice to the forehead has also been recommended.

2. ATROPHY OF THE OPTIC NERVE.—

Pathology.—Whether the atrophy be the result of changes within the eyeball or behind it, the nerve is invariably affected ultimately in its entire length. The nervous elements of the trunk are involved in all true cases, and there is a corresponding loss of function. The histological condition of the atrophied nerve varies somewhat, according to the nature of the pathological process producing it, and different appearances may be presented in sections through different parts of the same nerve-trunk. Thus, in *atrophy the result of a neuritis* we find the usual post-inflammatory changes at the seat of the inflammation, while the rest of the nerve may present the appearances found after a simple or non-inflammatory atrophic process. As previously mentioned, neuritis leads to hypertrophy of the interstitial connective tissue; the consequent contraction of the meshes in which the nerve-fibre bundles lie subjects the latter to pressure, interfering at first with their function, and ultimately with their vitality. The nerve-fibres involved finally either break down and are removed, or they undergo grey degeneration; in the former case, the diameter of the nerve is much reduced from contraction of the fibrous tissue.

In the case of a neuritis at or near the intraocular end of the nerve, the walls of the central blood-vessels are thickened, and their lumen is diminished—partly in consequence of this change in their walls, but mainly from the pressure exerted by the hypertrophied connective-tissue. In *simple atrophy* there is seldom much increase of connective-tissue. The nerve-fibres lose

their white medullary sheath by a process of granular fatty degeneration, while the axis-cylinders are usually retained, but converted into fine indistinct fibrils. There is, consequently, little change in the size of the nerve, which presents the appearance of a translucent, grey, gelatinous-looking cord. This 'grey degeneration,' as it is called, is the most common form of simple atrophy. According to some authorities, this degeneration is really dependent upon a 'medullary neuritis.' It may be *diffuse*, affecting the whole nerve uniformly; or *insular*, and varying much in extent in different sections. Occasionally, however, we find considerable thickening of the connective-tissue framework due to a sclerosis, which, though not clearly traceable to an inflammation, is probably the result of a very chronic form of neuritis. In other cases of simple atrophy, the smaller blood-vessels of the nerve-trunk are found immediately surrounded by masses of a peculiar, gelatinous-looking material, between which lie the degenerated nerve-fibres. There is little increase in the connective-tissue in this form, but the normal arrangement of the trabeculæ is destroyed. In the great majority of cases both nerves are affected, though one may be considerably in advance of the other. Unilateral optic atrophy is to be explained by the one-sided nature of the preceding inflammation or other local cause.

Causes.—All cases of atrophy of the optic disc may be divided broadly into two great classes—(a) *inflammatory* and (b) *non-inflammatory* or *simple*. (a) Those due to inflammation are traceable either to a papillitis, a post-bulbar neuritis, or to an inflammation of the choroid or retina. (b) Simple atrophy may be primary or secondary. The *primary* form is usually the result of a grey degeneration, commences independently of any local cause, and is characterised by the occurrence of visible atrophic changes consentaneously with gradual failure of vision. In the *secondary* form, the loss of vision precedes the atrophy. *Primary* atrophy not infrequently occurs in association with disease of the central nervous system, especially with locomotor ataxy, but occasionally also with cerebral atrophy, mania, general paralysis of the insane, congenital idiocy, disseminated sclerosis, and lateral sclerosis of the cord. When found uncomplicated with other nerve-lesion, the remote causes assigned are the same as those which are given for the occurrence of grey degeneration in the central nervous system; and it would therefore seem probable that, due to the

action of certain causes, grey degeneration may occur independently in the brain, spinal cord, or optic nerves, and may be confined to one or other of these situations. Accordingly, we find male adults of the neuropathic disposition, from thirty to fifty, predisposed to this form of atrophy. The more immediate causes mentioned are severe bodily fatigue and hardships, especially exposure to cold and insufficient nourishment, grief and anxiety, mental excitement and exhausting brain-work, irregular habits of life, sexual excess, &c. Frequently no cause can be assigned.

The *secondary* form of simple atrophy includes all those cases where an interruption of conductivity in one part of the nerve leads to subsequent atrophic changes in the remainder, as in cases of injury where the nerve is cut across or torn through. Secondary atrophy may also arise from interrupted blood-supply (as from embolism), and from mechanical pressure (as from tumour, inflammatory exudation, bone-spicules, foreign bodies, &c.). Strictly speaking, the changes in many of the inflammatory cases are also of this nature; a localised neuritis leading to secondary atrophy in the rest of the nerve-trunk. Syphilis is a productive cause of optic atrophy and may induce any of the inflammatory forms above mentioned, or may lead to a secondary atrophy (as from the pressure of a gummatous exudation at the optic foramen, &c.). We frequently also get a specific history in cases of simple grey degeneration.

Ophthalmoscopic Appearances.—All forms of optic atrophy are recognisable by the ophthalmoscope sooner or later, inasmuch as the intraocular end of the nerve is always ultimately involved. The elements of the optic disc which undergo the atrophic change, are the nerve-fibres and the capillaries. Atrophy of the capillaries is to be diagnosed by the pallor produced, while nerve-fibre atrophy is ophthalmoscopically recognisable when an atrophic excavation exists. This latter, however, is often absent, since the space formerly occupied by nerve-fibres may be filled, or more than filled, by connective-tissue growth. We judge of the atrophy chiefly, therefore, by the *colour*, and much caution must be exercised in the observation, as the disc varies considerably in this respect, in different individuals, within physiological limits. It is particularly unsafe to diagnose pathological pallor of part of the disc, unless the vision be correspondingly affected. The colour of the atrophied disc may be white or grey,

according to the amount of fibrous tissue present. Not infrequently it is of a bluish or greenish tint, probably from the presence of a thin film of connective tissue in front of its surface. Variation in tint alone is generally inadequate for a conclusion as to the causation of the atrophy, in so far as similar anatomical changes in the nerve may be the result of a neuritis and of a simple atrophy.

The *excavation* in atrophy comes quite up to the margin of the disc all round, and is to be recognised by a change in the level of the vessels. It is never very deep, and slopes gradually backwards from the edges, so that the condition might be termed 'saucering' in contradistinction to the deep, steep-sided 'cupping' found in chronic glaucoma. Its occurrence and its depth are determined—(a) by the size and form of a previously existing physiological cup; (b) by the degree of wasting of the nerve; (c) by the amount of new connective-tissue formed; and (d) by the contraction which has taken place in this latter. At the bottom of the 'saucer' the lamina cribrosa may be visible over a large area, or it may be quite concealed by the newly-formed tissue. Usually, the edge of the disc is well-defined, and the normal scleral ring is traceable all round. The central retinal vessels are in some cases much diminished in size; in others only very slightly, if at all. Apart from cases of embolism, the reduction may be caused by changes in the vascular walls, pressure on the artery from connective-tissue hypertrophy, or by atrophic changes, in the inner layers of the retina, interfering with the circulation through the larger branches which run there.

In the post-papillitic form of atrophy, the disc is usually white; its margin is distinct, but often irregular-looking from a loss of pigment due to choroido-retinal changes; the central vessels are often bordered by opaque white lines, and are considerably reduced in size; the excavation is absent or slight, and the lamina cribrosa is invisible. In the atrophy consequent on choroido-retinal changes, the disc has generally a peculiar opaque, yellowish-red, 'waxy' appearance, and the retinal vessels are greatly diminished in size and sometimes in number. In the partial atrophy from axial neuritis, the pallor is confined to the temporal half of the disc. For a description of the form of atrophy due to increased intraocular tension, see GLAUCOMA.

Symptoms.—The most prominent symptom in cases of optic atrophy is failure of vision. The nature of this failure has been

already described in cases of atrophy secondary to neuritis. In atrophy from choroiditis and retinitis the failure is usually gradual, central vision often remaining fairly acute while the rest of the field has become amblyopic. In the secondary form of simple atrophy the vision often fails suddenly; sometimes only one-half of the visual field is lost, as in some cases of pressure on the chiasma. In primary atrophy, the loss of vision begins gradually and proceeds slowly and continuously. Besides the central failure, there is marked contraction of the visual field, sometimes occurring in a uniform, concentric manner, but more frequently in the form of sector-shaped defects, usually situated above and to the outer side of the fixation point. Affection of the colour-sense is almost constant, green being generally the colour first confused, while later, perception fails for red, blue, and, lastly, yellow. In the final stage of atrophy all colour-distinctions are lost, but there is no constant relation between the degree of the loss of colour-sense and the amount of the amblyopia. The pupils are usually wide in post-papillitic atrophy, small in spinal cases, and often of medium size in other forms. *See* AMBLYOPIA; AMAUROSIS; PERIMETRY.

The *prognosis* is unfavourable in all cases of true optic atrophy, but it is relatively less so where the atrophy is dependent upon some cause which is either removable, or which may pass away spontaneously. In some of the post-papillitic cases, also, considerable improvement takes place, if the sclerosing process do not lead to excessive pressure on such nerve-fibres as may have escaped destruction by the inflammation. In very exceptional cases we may get a restoration of normal vision under treatment, the disc remaining in the condition of white atrophy. In marked contraction of the visual field, and in cases of long-standing amblyopia, little or no improvement is to be expected. In cases of primary atrophy, almost complete blindness usually occurs in from one to three years.

Treatment.—Where the atrophy is dependent on some general condition or toxic influence, the treatment must be regulated accordingly. Nervine tonics are said to be occasionally useful. Where the atrophic process has not gone too far, the continuous current is sometimes beneficial. One pole should be applied over the closed eyelids and the other over the supra-orbital nerve, the current being broken pretty frequently and the poles transposed. The smallest number of cells which gives the physiological light-flash on making and breaking the circuit

should be employed, and the whole sitting should last about five minutes and be repeated daily for at least a month. If no improvement take place in this time, either in central acuity or in visual field, this treatment may be abandoned. If any marked benefit result, the current should continue to be employed at intervals. The patient is quite capable of carrying on the treatment for himself, after having once been properly instructed.

TUMOURS OF THE OPTIC NERVE.—The intraocular end of the nerve may be the seat of large colloid outgrowths from the vitreous lamina of the choroid. It may also be affected secondarily in sarcoma of the choroid, or in retinal glioma, the former spreading along the sheath and fibrous framework, the latter in the medullary substance of the nerve. The nerve-trunk (including its inner sheath) may be the original seat of tumours, or it may be involved secondarily by the extension of growths arising in the outer sheaths or in the orbital tissue around. The most common form of tumour proper to the nerve is the myxo-sarcoma. It leads to proptosis, papillitis or simple atrophy, and early blindness; the movements of the globe are usually good, and there is little or no pain. The intracranial part of the nerves and the chiasma are especially liable to gummata, and the chiasma may also be the seat of a deposit of cheesy tubercle. In most cases of tumour of the optic nerve, excision of the eyeball and tumour will be required. *See* EYEBALL, Excision of the; ORBIT, Tumours of the.

INJURIES TO THE OPTIC NERVE.—The optic nerve may be injured in any part of its course, either as the result of a blow, stab, gunshot wound, or fracture of the sphenoid bone. A powerful blow on the side of the eyeball may cause the nerve to be torn away at its entrance into the globe. A stab or thrust into the orbit may cut or tear the nerve; or, again, may merely bruise it, cause an extravasation of blood within its sheath, or sever the central vessels outside its trunk. If a foreign body penetrate deeply, it may produce a fracture of the orbital walls, not infrequently breaking off and forcing backwards the clinoid process of the sphenoid bone, and thus leading to injury of the nerve. Similarly, gunshot wounds may implicate the nerve either in its orbital or intracranial course, and pellets or fragments of metal may penetrate the eyeball and become embedded in the papilla. Fracture of the base of the skull, as from a fall or severe blow on the head, occasionally causes injury to the optic nerve at the

optic foramen, or behind it if the clinoid process be displaced. Sudden complete blindness of the corresponding eye is usually the result of any severe injury to the nerve. If the solution of continuity be complete, permanent blindness is the consequence; if incomplete, we may get restoration of vision in part of the field. If the nerve be simply bruised or pressed upon, sight may be restored; but secondary changes may occur in such a case, leading to ultimate atrophy. The ophthalmoscopic appearances differ according to the position of the injury. If the central artery be cut or torn through, we find changes in the fundus similar to those met with in embolism of the central artery. In other cases, the disc remains normal in aspect until the atrophic process reaches it, when it gradually assumes the appearance of an ordinary secondary atrophy with normal vessels. The treatment of the recent injury must be based on general surgical principles. Later on, if the continuity of the nerve has been preserved, the measures recommended above in optic atrophy may be of some avail.

R. MARCUS GUNN.

ORBIT, Diseases of the.—ABSCCESS OF THE ORBIT may be caused by blows on the eye or the adjacent parts, causing an effusion of blood into the orbital cellular tissue; or by any violence producing fracture of the orbital walls; or by penetrating wounds of the orbit; by the lodgment of a foreign body in the cellular tissue of the orbit; or by the extension backwards of a suppurative inflammation of the lids or of the tissues in immediate contiguity with the eye, no matter how induced. Orbital cellulitis, brought on by any cause, may terminate in abscess of the orbit. Caries, necrosis, or orbital periostitis may lead to abscess of the orbit.

Abscess of the orbit may be either *acute* or *chronic*.

ACUTE ABSCESS OF THE ORBIT is marked by the rapidity with which the inflammatory symptoms are developed—deep-seated pain in the orbit extending around the brow, worse at one time, better at another, but never absent, and steadily increasing in severity. Any pressure on the eye, or even moving it, aggravates the pain. The eyelids become red, shining, and oedematous, and the conjunctivæ of the lids and globe vascular, swollen, and chemosed. The eye now begins to protrude slightly beyond the level of the other, and this protrusion increases with the inflammatory exudations until, at last, the pus makes its way to the

surface. The displacement of the eye is usually not directly forwards, but more or less downwards and outwards, or downwards and inwards, according to the part of the eye on which the abscess presses. With the increasing protrusion of the globe the sight may become impaired, from the strain which is exerted on the optic nerve. The orbital fold of skin above the lid becomes obliterated, and the upper lid so swollen and stretched in front of the bulging eye that it cannot be raised by the patient. Over the most prominent part of the swelling a careful examination with the fingers will detect fluctuation. The most usual spot for the pus to point at is rather to the inner side of the interval between the supra-orbital ridge of the orbit and the upper border of the globe. Occasionally, the suppuration is more or less confined to one or other side of the orbit, and it may then point at either the inner, outer, or lower border of the eye. When the abscess is small, there may be little or no displacement of the eye. With all these local symptoms there is always considerable constitutional disturbance. The skin is hot and dry, the patient has occasional rigors and frequently night sweats, he is restless, and his sleep is broken from pain.

CHRONIC ABSCESS of the orbit is distinguished by the slowness of the development of its symptoms, and frequently by the absence of any severe pain. It often happens that the patient does not even seek advice, until an increasing protrusion of the eye with some diminution of vision excites alarm.

The diagnosis of chronic abscess of the orbit is sometimes difficult, and it may be confounded with a sarcoma or some soft orbital tumour, the elasticity of which closely resembles fluctuation. When there is doubt, an exploratory incision should be made into the tumour, and the surgeon should be prepared to act at once on the information it will afford him. If it be an abscess, the incision should be enlarged sufficiently to give free exit to the pus; but if it should prove an orbital tumour, it should, if practicable, be removed without any further delay.

Treatment of Orbital Abscess.—As soon as it is clear that pus has formed, a free opening should be made into the orbit for its escape. The site for making the incision should be that spot where there is the most distinct swelling and fluctuation, and where the pus has a tendency to point. In making the incision into the orbit, it is a wise precaution to place one finger of the

left hand on the lid so as to feel the globe, and to pass the knife between the nail of the finger and the edge of the orbit, as, if the incision is carelessly made, it is quite possible to wound the eye. The best knife for the purpose is a Beer's or Sichel's cataract knife, as the point is very sharp and the blade very thin, and with it the incision can be made easily and with safety. After the incision has been made and the pus allowed to escape, a strip of oiled linen should be inserted a short distance into the wound, to prevent the lips uniting; or a small india-rubber drainage-tube may be placed in the wound. A warm linseed-meal poultice should then be applied. The strip of linen or the drainage-tube should be changed daily for two or three days, when they may be removed. It is only necessary to continue the linseed-meal poultice for about forty-eight hours, when a fold of lint, soaked in a solution of carbolic acid about 1 part in 100 of water, may be applied and covered with oiled silk. In most cases the cavity of the abscess soon closes, and the patient makes a good recovery. It occasionally happens, however, that the wound from the incision only partially closes, and a long sinus remains, from which a slight purulent discharge continues to drain. When this is the case, and when no fragment of necrosed bone can be detected by a probe to account for it, the use of a stimulating injection, such as Zinc sulphat. gr. ij. ad f3j., or Zinc chlorid. gr. j. ad f3j., thrown into the sinus with a glass syringe twice a day, will often prove of great benefit. If, however, a portion of dead bone is felt with the probe, time must be given to allow of its becoming detached, or at least partially loosened from the living structure; and then, after enlarging the orifice of the sinus, it may be removed with a pair of fine sequestrum-forceps, first using, if necessary, a gouge or an elevator, or a pair of fine cutting bone-forceps to separate any portion of bone which may be holding it.

PERIOSTITIS OF THE ORBIT may occur in two localities—(1) in the circumferential ridge of the orbit, and (2) in the walls of the orbit.

(1) When the ridge of the orbit is the part affected, the periostitis is generally due either to a blow on the edge of the orbit, or to some constitutional defect in the patient, as struma, when a portion of the bone, or of the periosteum covering it, without any apparent cause inflames. In either case an abscess forms, which continues for a long time to discharge a little pus and gradually contracts to a sinus, at the bottom of

which a piece of necrosed bone may be felt with a probe. Ultimately a scale of bone is exfoliated and the part heals, leaving a depressed scar, which is adherent to the subjacent bone.

(2) Periostitis of the walls of the orbit is generally *chronic*, and due to syphilis, although it undoubtedly may arise from injury, such as penetrating wounds of the orbit or foreign bodies within the orbit. Syphilitic periostitis of the walls of the orbit usually leads to the formation of nodes or the effusion of lymph beneath the periosteum. These nodes are not common, but when they do occur they often suppurate, and a portion of the subjacent bone either exfoliates or becomes carious. The most frequent position of a syphilitic node adjacent to the orbit is on the frontal bone, just over the brow, and rather to the outer side.

Acute periostitis of the orbit rarely occurs, but when it does it is generally due to injury—either blows, possibly causing fracture of the walls of the orbit; or penetrating wounds; or the lodgment of foreign bodies in the orbit.

Treatment.—As chronic periostitis which is not due to injury is almost invariably dependent on syphilis, in many cases dating back many years, the most useful medicine is the iodide of potassium, which should be given in the first instance in doses of from gr. iij. to gr. v. three times a day; but if these fail to do good, the dose may be increased to gr. viij. or gr. x. To relieve pain and favour the absorption of the effused lymph, an ointment of Extract. belladonnæ gr. lx., Unguent. hydrarg. 3vij. may be rubbed into the brow daily. If the pain be very severe, opiates may be given at night, or, if preferred, a subcutaneous injection of from gr. ¼ to gr. ½ of the acetate of morphia. If these remedies fail, the following mixture may be ordered—Hydrarg. perchlorid. gr. j.; Potassii iodid. gr. lx.; Tinct. calumbæ f3ij.; Aquæ destillat. ad f3vj. Dose—Two teaspoonfuls in a wineglass of water three times a day.

If the node within the orbit should soften and pus be formed, an opening should be made to give vent to it; and if a chronic discharge continue, and this be found dependent on a piece of dead bone not yet detached, the sinus should be syringed out once or twice a day with a weak solution of carbolic acid, about m.ij. ad f3j. As soon as the probe detects that the bone is loosened, the sinus should be enlarged and the exfoliated portion removed with a pair of forceps.

NECROSIS AND CARIES OF THE ORBIT.—Necrosis of a portion of one of the orbital bones is generally induced by an injury, or by an acute orbital abscess. Caries is usually produced by some constitutional taint, such as syphilis or struma. Both caries and necrosis may follow orbital periorbitis.

Treatment.—For necrosis, time should be given to allow the dead portion of the bone to become detached from the living structures; and then, guided by a probe, passed along the sinus by which the discharge escapes, an incision should be made down to the necrosed bone, which should be removed with a pair of fine sequestrum forceps.

When there is caries, the object of the treatment is to obtain healthy action in the carious bone, and thus produce cicatrization. The remedies must be both constitutional and local. If there be a syphilitic taint, the iodide of potassium, gr. iij. to gr. v., combined with ferri et ammon. citrat. gr. v. in water, may often do good, or the same doses of the iodide combined with gr. x. of the bromide of potassium may be given; or if these fail, other anti-syphilitic remedies may be tried. When caries is due to a strumous diathesis, cod-liver oil, and the syrup of the iodide or hypophosphite of iron will generally do good, especially if the patient can at the same time obtain sea air and a good nutritious diet.

GEORGE LAWSON.

ORBIT, Injuries of the.—**FRACTURE OF THE BONES OF THE ORBIT** may be produced by blows on the head or face, and either the roof, the inner wall, or the floor of the orbit may be fractured.

If the ethmoidal cells have been broken, there is frequently emphysema of the lids and surrounding parts, which is caused by the patient forcibly driving the air through the broken cells when he blows his nose. Fracture of the orbit is frequently associated with fracture of the anterior fossa of the base of the skull, when the presence of blood beneath the conjunctiva is sufficient to indicate that the fracture has extended into the orbit.

There is one form of fracture which is confined to the walls of the orbit, and which is very fatal. It is what may be termed a punctured fracture, and is commonly produced by a forcible thrust in the orbit with a sharp or semi-blunt instrument, such as the points of a pair of scissors, the stem of a long tobacco-pipe, the end of an umbrella, of a stick, or a foil. This accident has also been occasioned by a child falling on a

piece of slate-pencil which it had in its hand. The orbit is penetrated, and the end of the stick, or whatever it may be, is thrust against the roof or the upper part of the inner wall, which in some cases it simply fractures, whilst in others it breaks its way through the bone and penetrates the substance of the brain.

Even when the bones are broken but not penetrated, the sharp splinters usually create such an irritation of the brain and its membranes as to place the life of the patient in great jeopardy. When, however, there is in addition to the fracture a punctured wound of the brain, death is almost certain. It occasionally happens that a portion of the body which has penetrated the orbit and entered the brain has been broken off short, and the fragment which has been left behind has either not been detected during life, or, if discovered, could not be removed. The writer has seen both these conditions occur; in one case a piece of stick which had penetrated the brain through the orbit, and been broken off on a level with the bone, was only discovered at the post-mortem examination; and in a little child whose orbit had been penetrated by a piece of slate-pencil upon which it had fallen, the end of it was broken off flush with the roof of the orbit and could not be seized with forceps and withdrawn, for it broke under the pressure of the blades each time it was caught between them. One curious fact connected with these punctured fractures of the orbit is, that the severe nature of the injury is often overlooked; the external wound may be small, the immediate symptoms may be trifling, and the exact injury is not even surmised. The patient may be able to continue work for some hours, or even two or three days, before urgent symptoms oblige him to desist. Orbital cellulitis and suppuration may then come on, coupled with meningeal or cerebral irritation, and the patient may pass rapidly from slight delirium into complete coma, and die in a period varying from a few days to two or three weeks.

Treatment.—Absolute rest, both mental and bodily, in all cases in which fracture of the orbit is suspected, should be strictly enjoined. The patient should be kept in bed, and cold-water dressing or an ice-bag should be laid over the brow of the injured side; the bowels should be freely acted on by a purgative; and, if pain in the head come on, leeches should be applied to the temple and repeated if they do not give the desired relief. All stimulants should be forbidden, and only a limited diet be

allowed. If the fracture be a penetrating one, the end of the stick, or whatever it may be, should be carefully examined to see if any part of it has been broken off, and the wound should be also examined with the view of ascertaining if there be a foreign body within the orbit. If a foreign body be detected, it should be removed as soon as possible. If orbital cellulitis should come on, a free incision should be made into the cellular tissue of the orbit, so as to give vent to all inflammatory exudations before pus has actually formed. A good opening will frequently give immediate relief to the patient. When there is acute inflammatory action, the cold applications must be stopped, and fomentations of lead lotion—about one drachm of the liquor plumbi subacetatis to half a pint of hot water—be applied on absorbent cotton-wool, and covered with oil-silk; or a warm linseed-meal poultice.

FOREIGN BODIES IN THE ORBIT.—The lodgment of a foreign body in the orbit is a serious accident, as it involves a risk to the eye, and often places the life of the patient in jeopardy. The dangers are both immediate and secondary.

The immediate effects which may arise from a foreign body in the orbit are—(1) In its passage into the orbit it may injure the eye; (2) it may wound the optic nerve and cause blindness, without injuring the globe; (3) it may fracture the wall of the orbit, or it may penetrate the orbital wall.

The secondary effects which a foreign body in the orbit may produce are—

(a) If the foreign body has escaped notice, and been allowed to remain buried in the orbit, it may excite orbital cellulitis and abscess. This may induce a general inflammation of the eye, which may end in impairment of vision, or in destruction of the eye from suppuration.

(b) As the result of the orbital inflammation, a portion of the bones of the orbit may become necrosed; or the inflammation may extend backwards along the orbital periosteum to the membranes of the brain, and destroy life by meningitis, tetanic convulsions, or abscess of the brain.

A foreign body may enter the orbit at any part around the eye, but it generally passes in somewhere between the upper or inner side of the eye and the roof or inner wall of the orbit. If small, it usually buries itself in the loose fat of the orbit, but, if large, it will occasionally become fixed by either penetrating the globe, or by becoming wedged between the globe and

its muscles, or by the end of it entering one of the ethmoidal or frontal sinuses, or by penetrating into the antrum.

It has occasionally happened that a foreign body has been lodged in the orbit and one of the adjacent cavities, without the patient having suffered any great inconvenience from its presence. Mr. Brudenell Carter has related a case in which a large piece of an iron hat-peg was impacted in the orbit and the antrum of the opposite side, and remained there for a number of days without the patient being aware of its presence. It was then extracted, and the man made a rapid recovery without any impairment of the sight of the eye. In February, 1869, the writer extracted from a patient, æt. 28, the iron breech of a muzzle-loading gun, which had been impacted for twelve years in the right frontal sinus and upper part of the nose. The patient recovered without a bad symptom. In 1877 the writer extracted a piece of stick from the orbit of a child æt. 3, which had penetrated the orbit seven weeks previously, and had produced orbital cellulitis and suppuration.

Treatment.—Whenever there is reason to believe that there is a foreign body in the orbit, an attempt should be made to find and remove it. To this rule, however, there are exceptions, as when the foreign body is a small shot, or a fine scale of metal which may have flown off from a rivet or a chisel, and passed into the orbit without injury to the eye. The almost sure impossibility of finding a small fragment of metal in the fat of the orbit forbids the attempt to search for it. The presence of small shot or small pieces of metal rarely produces symptoms of irritation, whilst an extended trial to find them might induce orbital cellulitis with abscess.

Having decided that there is a foreign body in the orbit, the following operation for its removal may be performed:—The outer canthus should be freely divided, either by a pair of scissors or with a scalpel, to allow of the upper lid being completely turned up, or the lower one drawn down, according to the locality in which the foreign body is lodged. The reflection of conjunctiva between the lid and the globe is then to be divided over the spot where the foreign body is suspected to be lying. A probe or the little finger may then be passed through the wound into the orbit by the side of the eye, and the object being felt, it may be seized and drawn out with a pair of sequester-forceps. If the foreign body has become entangled with one of the

recti muscles, or from any other cause one of these should interfere with its easy withdrawal from the orbit, it is better at once to divide the muscle with a pair of scissors as close as possible to the globe, rather than use any force to overcome the resistance it may be causing. The lids are then to be replaced, and closed with a light compress of lint and cotton-wool, and fastened in position with a roller.

INJURIES TO THE OPTIC NERVE. See *OPTIC NERVE, Diseases and Injuries of the.*
GEORGE LAWSON.

ORBIT, Tumours of the.—Tumours of the orbit may be considered under four headings—

I. Tumours which originate within the orbit.

II. Congenital tumours of the orbit.

III. Tumours which have their origin at some site beyond the eye or the orbit, and which by mere growth have extended into the orbital cavity.

IV. Tumours which primarily originate within the eye, and afterwards extend into the orbit; or which recur in the orbit after the eye, the primary seat of the growth, has been excised.

Each of these classes may be considered in detail.

I. TUMOURS WHICH ORIGINATE WITHIN THE ORBIT.—The presence of an orbital tumour is usually indicated by a change in the position of the eye, which is more or less protruded, and generally also displaced in one or other direction, either upwards or downwards, inwards or outwards, according to the locality of the orbit from which the growth springs. All sight may be destroyed by the pressure of the tumour on the optic nerve, or, if there be great protrusion of the eye, by the stretching of the optic nerve. It is, however, often astonishing to what an extent the eye may be projected and the optic nerve stretched without producing great impairment of sight; and how the lost sight is often regained after the eye has been restored to its proper position by the removal of the growth.

To examine an eye which is protruded the patient should be placed in a chair with his head thrown backwards, whilst the surgeon, standing behind him, raises the two upper eyelids with one finger of each hand, and at the same time directs the patient to look downwards towards his feet. From this position, above and behind the patient, the surgeon can glance down the face and contrast the level of the two eyes with each other, and compare the promi-

nence of the protruded eye with the brow and the side of the nose. In this manner a correct estimate may be made of the extent and the direction of the protrusion. When the proptosis is slight, it is often difficult to determine whether the protrusion is real or only apparent, as any oedema of the lids or of the conjunctiva will give a prominent appearance to the eye. Having formed an opinion of the degree of the proptosis, a careful examination should next be made, with the fingers, of the space between the globe and the margin of the orbit, to ascertain if any projecting edge of a tumour can be felt, and if so, to endeavour to obtain some information as to its nature by noting whether it is elastic, hard, or fluctuating.

The tumours which originate within the orbit and external to the eye are:—(a) Orbital sarcomas, growing from the periosteum of the orbit. (b) Tumours of the optic nerve. (c) Scirrhus tumours of the orbit. (d) Bony and cartilaginous tumours of the orbit. (e) Fibrous tumours of the orbit. (f) Cysts of the orbit.

(a) **ORBITAL SARCOMA.**—*Spindle or round-celled sarcoma* usually grows from the periosteum of the orbit, starting first at one point, and then extending itself so as frequently to involve the greater part or the whole of the periosteum. The disease first manifests itself either by some proptosis of the eye, or by diplopia caused by some slight displacement of the globe, or by pressure on the ocular nerves producing palsy of one or more of the ocular muscles, or by pressure on the optic nerve inducing some defect in sight. As the growth advances, the bulging of the eye increases until it is protruded beyond the lids. When the eye by its prominence has lost the protection of the eyelids, the cornea, from exposure, will inflame and ulcerate, and the eye will be destroyed. In some cases, the tumour as it grows will force its way between the globe and the orbit, and it can then be both seen and felt as a hard mass pressing forward beneath either the upper or the lower eyelid, according to the locality in which it has extended itself.

Prognosis.—In all cases of orbital sarcoma the prognosis is unfavourable, as the disease is very apt to recur, and distant internal organs to be invaded by it. If, however, the growth be completely excised at a moderately early stage of the disease, and the chloride of zinc paste be freely applied, a good chance of recovery is afforded the patient. The writer has had several cases of undoubted orbital sarcoma which

he has thus treated, and the patients have lived some years without any recurrence or manifestation of the disease elsewhere.

(b) TUMOURS OF THE OPTIC NERVE are rare. See OPTIC NERVE, Diseases and Injuries of the.

(c) SCIRRHOUS TUMOUR OF THE ORBIT is a rare affection, and it has been doubted whether true scirrhous ever does occur in the orbit. The writer has had two cases of scirrhous of the orbit under his care. The first case was in a woman from whom he removed a scirrhous tumour of the orbit, and at the same time a secondary scirrhous tubercle in the skin in front of the ear and lying over the parotid gland. After excising the tumour he freely applied the chloride of zinc paste, and the whole of the bones of the orbit were detached in one piece, and are to be seen in the museum of the Middlesex Hospital. The operation was performed in February, 1866, and the patient up to the present time, January, 1885, has continued well and free from any recurrence of the disease.

The second case was also in a woman in the Middlesex Hospital. She had a tumour of the orbit which caused great proptosis. The same treatment as in the preceding case was adopted, and portions of the orbital bones exfoliated. The parts healed up, and the patient left the hospital apparently well. A few months afterwards it was found that she had a scirrhous tumour in each breast. It is probable that these tumours existed at the time of the operation on the orbit, and that she had not noticed them. About twelve months afterwards the patient died at her own home with all the symptoms of secondary cancer in the abdominal viscera. There was no return of the disease in the orbit.

Treatment of Sarcomatous, Scirrhous, or Recurrent Tumours of the Orbit.—If the tumour is small and grows from the periosteum near the margin of the orbit, it may be dissected out and the eye, if possible, saved. It is, however, only in exceptional cases that this course can be adopted. As a rule, it is necessary first to enucleate the eye, and then to proceed to excise the tumour, and this is most conveniently done with a pair of small but strong scissors, curved on the flat, and a pair of toothed forceps. Having excised as much of the tumour as can with safety be removed, the actual cautery should be freely applied to those parts of the growth which may still remain, and to all the bleeding points. When all hæmorrhage has ceased, the chloride of zinc paste, the formula for

which is given below, spread on small pieces of lint, should be laid evenly over the whole surface from which the tumour has sprung. A small pledget of cotton-wool should then be placed in the orbit, and over this a fold of dry lint, which is to be held *in situ* by a bandage tied firmly around the head. Before the patient awakes from the anæsthetic, from one-sixth to one-third of a grain of the acetate of morphia should be injected subcutaneously into the arm, to dull the severe pain which usually follows this proceeding.

Where the writer has excised the eye with the orbital tumour and has been able to save the conjunctiva which covered the globe, he has adopted the following method of applying the chloride of zinc paste, in order to avoid the sloughing of the eyelids which so generally happens from the caustic extending to them.

After the eye and tumour have been excised, pressure is to be made in the orbit until all bleeding has ceased. The mouth of the conjunctival bag, from which the eye has been enucleated, is now to be held open with two pairs of forceps, whilst the chloride of zinc paste spread on lint is plastered round the sides of the orbit. A small piece of cotton-wool is next introduced to keep the strips of lint *in situ*, and the mouth of the conjunctival bag is closed over the whole by a single continued suture. A layer of oiled lint is then placed over the conjunctiva, and upon this the lids are closed and kept in position with a compress of lint and a roller. In this way he has destroyed all that was required without affecting the lids.

On the day following the operation the bandage may be removed, and if there is much tension of the lids from the stuffing within the orbit, some of the cotton-wool may be gently drawn out, and, a piece of clean lint having been laid over the parts, another bandage should be lightly applied. The remainder of the cotton wool should be taken away on the second day, and a little fresh absorbent wool laid loosely within the orbit to absorb the discharge, as soon as suppuration commences. This dressing should be repeated daily, but the pieces of lint, on which the chloride of zinc has been applied, should not be removed until suppuration has quite loosened them from the surface against which they were placed. After about ten or twelve days the sloughs will separate from the orbit, and if any suspicious-looking granulations spring up, they should be touched with the solid chloride of zinc or with the potassa cum

calce. The writer has three times seen epileptic convulsions follow within thirty-six hours after the operation, but they have in each instance ceased shortly after the removal of the cotton-wool and chloride of zinc from the orbit. The fits did not recur, and the patients perfectly recovered. If convulsions should occur, the chloride of zinc dressing should be at once removed and the cavity be syringed out with a little dilute acetic acid, about one drachm to the ounce of water.

In removing tumours from the orbit, it should be remembered that the orbital plate of the frontal bone is frequently thin and soft from the pressure of the growth against it. Special care should therefore be taken during the operation to avoid applying force with any instrument against the roof of the orbit. Twice the writer has been present when brain-substance has been brought away with portions of the tumour. On each occasion there is no doubt that, in places, the orbital plate had completely disappeared before the pressure of the tumour, which had grown through it.

The following is the formula for making the chloride of zinc paste:—

Pasta Zinci Chloridi. (Ph. Middlesex Hospital.)

This paste is prepared by first making the *Liquor zinci chloridi cum opio* as follows:—

Zinci chloridi, ʒxvj.; *Pulveris opii*, ʒiss.; *Acidi hydrochlorici*, fʒvj.; *Aquam bullientem ad Oj*.

Macerate the opium in twelve ounces of the boiling water for twelve hours, add the acid and filter, then dissolve the chloride of zinc in the filtered liquid and make up to twenty ounces with distilled water.

To this, flour is added, to render it of a proper consistence, as follows:—

℞ *Liquoris zinci chloridi cum opio* fʒj.
Farinæ tritici gr.cxx.

Mix smoothly in a mortar, and heat over a water-bath until of a proper consistence.

(d) BONY AND CARTILAGINOUS TUMOURS OF THE ORBIT are of two kinds—1. Those which are attached within the orbit by a small bony pedicle. They may be composed entirely of bone, or of both bone and cartilage. These growths may be as large as a walnut, and yet from their slender connection with the orbit they have been easily detached. 2. Those bony tumours which grow within the orbit, but which have a broad base, and occasionally extend through the orbital bones into the cranial cavity. Some of these growths are of an ivory hardness.

Treatment.—In all cases of bony tumour of the orbit an exploratory examination should be made, but with the understanding that the operator has discretionary power to endeavour to remove the growth, or to leave it, as he may deem advisable. Without such an exploratory operation, it is impossible to decide whether the tumour is attached to the bony walls by a thin pedicle or a broad base. The writer has, on several occasions, found that the tumour, although rather large, and apparently fixed to the orbital walls, had only a small pedicle, and was removed without difficulty. On the other hand, he has found the tumour with such a broad base that he decided to leave it, rather than run the risk of fracturing the orbit by an attempt to remove it. On one occasion, with a small chisel he succeeded in splitting off from the inner side of the orbit a small bony tumour, which had a base three-fourths of an inch long and a quarter of an inch wide. The patient did well, and the tumour did not recur.

A very instructive case of a large orbital and intracranial ivory exostosis is reported by Mr. Tweedy in the *Royal London Ophthalmic Hospital Reports*, vol. x. p. 303, in which he succeeded in removing the orbital portion of the growth by a drill worked by a powerful Archimedean screw. He says: 'By means of drills of various sizes, I managed to bore a large number of tunnels in various directions through the base of the growth, parallel with the upper and inner walls of the orbit. I then cut through the narrow bony septa between the borings with a stout carpenter's chisel. When the chisel had made its way deep enough to act as a wedge, I gave a few energetic blows with the mallet, and succeeded in breaking off the whole of the orbital portion of the growth. When this was accomplished, the orbital cavity seemed almost normal in size and shape, though it was obvious that a large mass, forming the base of the growth, still remained behind.'

The patient did well until one month after the operation, when head-symptoms came on, and he rapidly died comatose. On the post-mortem examination it was found that the greater part of the exostosis was in the left anterior cranial fossa. It had originally sprung from the left frontal sinus, and had grown chiefly upward.

In all operations for orbital tumours the surgeon should be provided with small bone-forceps, a bone-chisel, a gouge, an elevator, and a small Archimedean drill.

(e) **FIBROUS TUMOURS OF THE ORBIT** are not common, still they do occur and it is of importance to recognise them, as the prognosis is much more favourable than in the sarcomatous growths which form the majority of the orbital tumours. The fibroid tumour grows from the periosteum of the orbit, to which it is frequently attached by a pedicle of less dimensions than the mass of the tumour; in some cases the pedicle is very small. When completely removed with the pedicle and the portion of the periosteum from which it springs, the probability is that the tumour will not return; but this entire removal of the growth is often difficult, and sometimes impossible to be accomplished from the attachment to the periosteum being far back in the orbit. In some cases, therefore, the growth recurs, and probably from a small portion of it having been left behind at the time of the operation.

There is, however, another form of fibroid tumour which may occur in the orbit, and which is recurrent, but not necessarily in the site from which it first grew. It may reappear in other localities, generally selecting for itself some fibrous expansion from which to sprout. The writer has met with only one case of this kind; it is reported in full in the *Royal London Ophthalmic Hospital Reports*, vol. vi.

Symptoms and Treatment.—In the cases which the writer has seen there has been some proptosis of the eye, and the tumour has made its way forward between the globe and the orbit, and bulged into the lid. The diagnosis of the nature of the tumour cannot be made before the operation, although a certain amount of mobility under the fingers suggests that the growth may be fibroid.

In such cases the tumour may frequently be removed without excising the eye. An incision should be made through the lid near the margin of the orbit, so as to expose freely the surface of the tumour, and then with a little care the tumour may be isolated and traced backwards to the part from which it springs, and be detached with a portion of periosteum, if near the anterior surface of the orbit; or if it springs from deep in the orbit, its pedicle may be divided with a pair of scissors. The wound of the lid may be then united with one or more fine sutures.

(f) **CYSTS OF THE ORBIT** are far less frequent than the solid orbital tumours. They are of various kinds—(1) Serous cysts; (2) hydatid cysts; (3) dermoid cysts.

(1) **SEROUS CYSTS** within the orbit are so rare that it is probable that some of the cases which have been described as serous cysts have really been hydatid. A very interesting case of serous cyst in the orbit was recorded in the *Royal London Ophthalmic Hospital Reports*, vol. i., by the late Mr. Poland.

(2) **HYDATID CYSTS OF THE ORBIT** are comparatively rare, yet many cases have been recorded. Lawrence, in his *Diseases of the Eye*, relates the case of a man, æt. 42, who was under his care in the London Ophthalmic Hospital in 1820, with protrusion of the globe. By an incision into the orbit he removed half a teacupful of hydatids. In the *Royal London Ophthalmic Hospital Reports*, vol. iv. Mr. Hulke has also recorded a case of hydatid cyst in the orbit.

The writer has had two cases of hydatid cyst in the orbit. The first case, recorded in the *Clinical Society's Trans.*, vol. ix., was remarkable from the 'choked optic disc,' which was produced by the pressure of the hydatid cyst on the optic nerve in the orbit, and the fact that the great engorgement of the optic disc disappeared after the cyst was evacuated by puncture. The second case is recorded in the *Royal London Ophthalmic Hospital Reports*, vol. x.

Symptoms.—Proptosis of the eye, and a tumour which can be felt with the fingers projecting between the edge of the orbit and the globe, more or less rounded in outline, with a smooth surface, and imparting to the fingers a sense of fluctuation; impairment of sight, rapid growth of the tumour with pain, which is frequently recurrent in its early formation, and no inflammatory action.

The shape and feeling of the tumour would indicate that it was a cyst, whilst the rapidity of growth, the pain in its early stages, with the absence of inflammatory action, would suggest that the tumour might be an hydatid. No positive diagnosis can be formed without an exploratory puncture either with a fine knife or a trocar. It occasionally happens that an hydatid tumour will remain stationary for some years and then take on rapid action, but this is not the usual course. These tumours generally develop steadily, and with increased growth there is an increased protrusion of the eye.

Occasionally, an hydatid tumour will inflame and suppurate spontaneously, and then all the symptoms point to orbital abscess.

For treatment see below, *Treatment of Cysts of the Orbit*.

(3) DERMOID CYSTS OF THE ORBIT are extremely rare. A very remarkable case of the kind was recorded by Mr. S. Barnes, surgeon to the Devon and Exeter Hospital in the *Médico-Chirurgical Transactions*, vol. iv. p. 316.

The usual situations for dermoid cysts adjoining the orbit are—at the upper and outer margin, and at the lower and inner edge of the orbit, just over the nasal process of the superior maxillary bone. They are congenital, and although to the touch they appear superficial, they are really deeply placed, lying in a depression of the bone beneath the orbicularis and often very adherent to the surrounding parts. They are filled with sebaceous material, and contain numerous hairs. These cysts, when large, will sometimes extend deeply into the orbit, and their removal then is frequently attended with considerable difficulty.

Treatment of Cysts of the Orbit.—In all cases, if practicable, the cysts should be removed entire. A free incision should be made over the most prominent portion down to the cyst wall, when it can often be enucleated; or, if not, it may be carefully dissected away from its surrounding attachments. When, from the position of the cyst in the orbit and the prolongations of it between the orbital muscles, it is found impossible to get it completely away, the cyst should be freely opened, and either an india-rubber drainage-tube or a piece of lint dipped in carbolic oil should be inserted into its cavity, to keep the cut edges from uniting and to allow of the free escape of all inflammatory products. The cavity should be washed out daily with a weak solution of carbolic acid.

In hydatids of the orbit, a free incision should be made into the tumour, and, after the fluid has escaped, the finger should be introduced into the cavity, and if possible the whole cyst be turned out; but, failing to accomplish this, the wound should be kept open by a large drainage-tube, and the cavity washed out daily with a solution of carbolic acid, about 1 in 80 parts of water.

II. CONGENITAL TUMOURS OF THE ORBIT are developmental growths. They originate during embryonic life *in utero*, and continue to grow after birth.

The following is an abstract of the report of the only case of this kind which has come under the writer's care. In May, 1882, he excised the eye of a child only two days old, on account of a congenital tumour of

the orbit, which had completely extruded the eye from between the lids. The little patient was taken to the Royal London Ophthalmic Hospital, suffering from complete exophthalmos, which was congenital, and evidently due to an orbital tumour. The eye was removed, and for a time the patient did well. The child lived into the middle of the August following, and was in fairly good health until within two days of its death, when convulsions came on, which were followed by coma. The post-mortem and microscopical examinations were made by Mr. Milles, then curator of the museum. The following is an abstract of his report:—A large tumour was found projecting from and filling up the right orbit. On opening the skull, the upper surface of the brain and its membranes were quite healthy. On the under surface there was a distinct impression in the right middle lobe, produced by the projection of several cysts from the sphenoid bone. There was well-marked basic meningitis, confined chiefly to the right side. The tumour seemed to have originated in the body of the sphenoid bone, and to have grown forwards, filling up the cavity of the orbit, and pushing the eye in front of it. The tumour was pretty solid, but contained numerous cysts in its substance. Under the microscope, the tumour was found to consist of several varieties of tissue in different stages of development. The most noticeable were patches of hyaline cartilage of a spherical or oblong shape; these were often surrounded by a zone of spindle cells, with a distinct gradation from cartilage cells. Numerous cysts of all sizes were scattered through the tumour. The walls of the cysts were usually lined by pavement epithelium. In places, small cysts were seen to be projecting from the walls of the larger ones. The more solid part of the tumour consisted of masses of round cells like embryonic tissue, spindle cells, and more fully developed fibrous tissue. There was evidence of formation of glandular structure at several parts. The microscopical examination showed that the tumour was evidently one of embryonic origin, with an attempt to develop into the lower forms of connective tissue and gland-structure.

Mr. T. Holmes has recorded in the *Pathological Transactions*, vol. xiv. p. 248, the successful removal of a congenital tumour of the orbit, from a child æt. seven weeks. On examination, the tumour was found to consist of 'a large mass of substance much resembling udder, of a hard uniform feel and white colour—not in any

respect resembling malignant disease.' Numerous cysts, containing thin serum, had been laid open. Other smaller solid masses lay in the neighbourhood of the principal tumour. Under the microscope the solid portion of the tumour showed nothing except fibrous tissue and simple nuclei.

III. TUMOURS WHICH HAVE THEIR ORIGIN AT SOME SITE BEYOND THE EYE OR THE ORBIT, AND WHICH BY MERE GROWTH HAVE EXTENDED INTO THE ORBITAL CAVITY.—These growths include tumours which spring from the antrum, the frontal sinus, the lacrymal canal, or from some portion of the bones which help to form the base of the skull, as the naso-pharyngeal polypi. They will be found described under their respective headings.

The other tumours of the orbit are distension of the frontal sinus from pent-up secretion and pus (*see* FRONTAL SINUS, Diseases of the); pulsating exophthalmos, or so-called ORBITAL ANEURISM; venous nævi of the orbit (*see* NÆVUS).

IV. TUMOURS WHICH ORIGINATE WITHIN THE EYE, AND AFTERWARDS EXTEND INTO THE ORBIT; OR WHICH RECUR IN THE ORBIT AFTER THE EYE, THE PRIMARY SEAT OF THE GROWTH, HAS BEEN REMOVED:—(a) Sarcoma and melanotic sarcoma of the choroid; (b) glioma of the retina.

(a) SARCOMA AND MELANOTIC SARCOMA OF THE CHOROID are essentially the same, the only difference being the addition to the latter of pigment, which is scattered in varying quantities between the sarcomatous cells. The identity of sarcoma and melanotic sarcoma is illustrated by the changes which sometimes occur in the growth of the tumour. Whilst confined within the globe, the sarcoma may be deeply coloured with pigment, but, having burst through the sclerotic, the tumour may grow with increased rapidity, and the extra-ocular portion remain white. Although a large number of the sarcomas which spring from the choroid are pigmented, yet the writer has excised many eyes in which the growth was white.

The early symptoms of sarcoma of the choroid are usually not noticed by the patient, unless the growth originate near the yellow spot of the retina, when an impairment of sight first draws attention to the eye. This is often discovered suddenly from the sound eye being accidentally closed, when it is noticed that a portion of the field of vision is more or less defective. This impairment of the field is due to a commencing detachment of the retina from the pressure of the growth behind it. With

the advance of the tumour the field of vision becomes more contracted, the area of the blind portion increases, the acuteness of vision of the rest of the retina diminishes, until ultimately the eye becomes blind. During the early development of the symptoms there is no pain; it is only when the growth has attained a sufficient size to exercise pressure on the lens, ciliary body, and iris that pain is produced. When once started, the pain increases with the growth, and becomes excessive when the globe is distended by it.

It is seldom that the patient seeks advice until there is some detachment of the retina from the pressure of the growth behind it. That the case is not one of simple detachment of the retina may be sometimes determined at once by the ophthalmoscope, when the vessels of the detached retina may be clearly recognised, whilst behind the semi-transparent retina a series of vessels which are not retinal, but which belong to the new growth, may be made out. In the *Royal London Ophthalmic Hospital Reports*, vol. iv., is recorded a case in which Sir W. Bowman was able to distinguish the vessels on the surface of the tumour from the vessels of the detached retina in front of it. It is, however, only in an advanced stage of the disease that this means of diagnosis can be available. The most important point in diagnosing a detachment of the retina caused by a tumour of the choroid is the state of the tension of the eye. As the disease advances there is generally an increase in the tension of the eye, and this glaucomatous state is associated with pain, which may vary from a slight sense of aching to an acute neuralgia in the eye, and extending over the brow and forehead. An eye with failing sight, a partial detachment of the retina and an increased tension, is very suggestive of an intraocular tumour, even though the growth itself cannot be seen with the ophthalmoscope.

It is often impossible to diagnose the glaucomatous condition which is induced by an intraocular tumour from an ordinary attack of glaucoma, as the accession of pain is frequently sudden, and, when seen by the surgeon, the media may be so dull that the fundus of the eye cannot be seen; and the distended episcleral vessels and more or less dilated pupil, with increased tension of the globe, present all the appearances of a case of subacute glaucoma.

Such cases have frequently been treated by iridectomy, and the true cause of the tension has been only discovered when

the eye has been afterwards excised from the iridectomy having failed to give any relief.

As the tumour grows, it gradually fills the globe and displaces the structures within the eye which are in front of it. The retina is extensively or completely detached, and the lens is pressed against the iris, and the iris bulged towards the cornea. Frequently the globe loses its normal shape, and dark bulgings are seen in the ciliary region. The tumour next makes an exit for itself. Either the cornea grows dull, then ulcerates, and through the opening the tumour protrudes; or else it forces its way through the sclerotic, either in the ciliary region or in a more posterior part of the eye. Having escaped from within the globe, the tumour seems to grow with an increased vigour; if it has burst through the globe anteriorly, its surface after a time ulcerates and bleeds, and assumes an appearance which has given to it the name of 'fungus hæmatodes.'

The attacks of hæmorrhage increase in frequency with the advance of the disease, until at last the patient sinks, worn out with pain and loss of blood. If the tumour has escaped through the sclerotic posteriorly, it grows rapidly in the cellular tissue of the orbit, and protrudes the eye; and this protrusion is sometimes to such an extent that the cornea will ulcerate and suppurate, from the exposure caused by the lids being unable to close over the eye.

Prognosis of Sarcoma of the Eye.—The prognosis depends very much on the period of the disease at which the eye is removed. If the disease be detected early and the eye be at once excised, there is a reasonable hope that there will be no recurrence in the orbit, and that years may elapse before there is a recurrence in any of the internal organs; indeed, that the patient may live many years and die of some other disease before any secondary deposits have taken place in the liver, lungs, or other organs. When the eye has been removed at an early period of the growth, the operation often seems to create a pause in the progress of the disease, which may extend over a variable length of time—certainly in some cases over ten years. Patients may die from secondary sarcomatous deposits in the liver and other organs ten and twelve years after the eye has been excised for an intraocular tumour, and without any recurrence in the orbit.

Dr. Knapp, in an excellent treatise on intraocular tumours, mentions several cases of a prolonged freedom from recurrence of

the disease after the eye had been excised. 'Prof. Dor's patient, fifty-six years of age, had in the year 1858 first noticed a blank portion in the field of vision of his right eye. The enucleation was made in January, 1860, whilst in a state of glaucomatous inflammation. The eyeball was slightly enlarged in its dimensions; the tumour, a melanotic, tough, fusiform-celled sarcoma of the choroid. . . . Nine years after the operation the patient was perfectly well.' Further on Dr. Knapp says:—'Professor Weber reported in the *Med. Naturhistorische Verein*, in Heidelberg, that both of the cases of choroidal melanosis were still perfectly well—one thirteen, the other twenty years after the operation. Mr. Hulke excised the eye of a gentleman in April, 1862, for a white spindle-cell sarcoma of the choroid, and the patient nine years afterwards was in perfect health.' These cases, no doubt, are rather exceptional, but still they sustain the hope that, if the eye be excised at an early stage of the disease, no recurrence may take place, or certainly that the patient may enjoy an immunity for many years.

When recurrence of the sarcoma occurs internally, there is scarcely an organ in the body which may not be involved by the secondary deposits. The liver, the lungs, the kidneys, the lumbar glands, the heart, and the brain may all become the seat of sarcomatous deposits.

In the museum of the Middlesex Hospital there is a series of preparations of secondary melanotic deposits in the different internal organs, which were taken from the body of an elderly female patient who had had a primary melanotic sarcoma of the choroid of the left eye. The right ventricle of the heart contained a mass of the secondary black sarcomatous deposit, which occupied the whole thickness of the wall and projected into the ventricular cavity. Both lungs and pleuræ were studded with the same black deposit; the seventh rib was the seat of a similar deposit. The liver and kidneys were affected, like the lungs, with large black deposits, and the spleen was the only internal organ that appeared healthy. In the sheath of the rectus there was a melanotic mass, the size of a pigeon's egg, which seemed to have no attachment. Throughout the body many of the glands were infiltrated with pigment, and were thus visible through the skin, though only slightly enlarged.

Treatment.—Excise the eye as soon as possible after the tumour of the choroid has been detected; even though the tumour be

no larger than a pea, and the sight of a portion of the retina good, yet there should be no delay. The earlier the eye is removed, the better for the patient. If the tumour has burst through the coats of the eye and has extended into the orbit, the chloride of zinc paste should be applied as recommended under *Treatment of orbital sarcoma*. The mode of application of the chloride of zinc must depend on the extent of the tumour in the orbit and the degree of apparent infiltration of the tissues with it. When the tumour has only just burst through the globe, and can be removed in its entirety, a thin layer of the paste spread on thin linen or cambric will probably be sufficient; but when the extension of the tumour into the orbit has been large, the chloride of zinc paste must be applied freely.

(b). GLIOMA OF THE RETINA is a disease of early life, and, in the writer's experience, is limited to early childhood. The writer has seen cases in which it was congenital, and he has not met with a case of retinal glioma which originated in a child beyond the age of five years. In appearance a glioma very closely resembles brain-substance; it is soft, of a white or yellowish white colour, and springs from the connective-tissue (the neuroglia) of the retina.

In structure it consists of a finely granular or amorphous intercellular substance, in which are embedded spherical, roundly oval, and occasionally spindle-shaped cells. It is usually of rather slow growth, extending over a period of from one to two years before it completely distends the globe and bursts through the sclerotic or cornea. As it grows, portions of it undergo fatty degeneration and become so soft as to be almost fluid, whilst other parts become chalky or calcareous. The disease spreads by infection, which travels along the optic nerve, and after death a similar growth is frequently found in the brain in direct communication with the optic tracts. In a child who had been under the writer's care, and had died from a recurrent glioma, a tumour was found within the skull, which had extended backwards from the mass within the orbit, and pressed upon, but was not connected with, the brain. The preparation is in the Middlesex Hospital Museum, and the case is reported in the *Transactions of the Pathological Society*, 1884-5. Glioma seldom produces secondary deposits in the abdominal or thoracic viscera; but Knapp has recorded one case in which there were secondary gliomas in the liver, lungs, and diploë of the bones of

the cranium. (Knapp *On Intra-Ocular Tumours*.)

Glioma is very recurrent, and is very apt to appear in the other eye after the eye in which it started has been removed, and also to recur in the orbit. There are exceptions to the recurrence of glioma after the diseased eye has been removed. In 1872 the writer excised the right eye of a child, æt. two years and eight months, on account of a glioma of the retina, and after more than seven years there was no return of the disease.

Symptoms.—Dilatation of the pupil with diminution of sight. In the early stage of glioma there is no pain. The disease is usually first discovered by the nurse or the mother noticing a bright yellow reflex from the fundus of the globe, and then, on closing the sound eye, it is found that the affected one is almost, if not completely, blind. The refracting media are generally so clear that the tumours can be easily seen. As the disease advances there is increased tension of the globe, and then the eye becomes painful and the child restless, frequently crying and starting in its sleep. The lens and the iris are pushed towards the cornea, and the pupil becomes dilated and inactive. At a later stage of the disease the lens becomes cloudy and the cornea dull, and the tumour bursts its way through the globe and forms a fungating mass, from which there are frequent recurrences of hæmorrhage; and the child dies, either worn out by pain and exhaustion, or from meningitis caused by an extension of the disease within the skull. If the eye be examined with the ophthalmoscope when the disease is in a comparatively early stage, the glioma will be seen occupying a limited portion of the retina, and with blood-vessels on its surface which clearly belong to the new growth. In the immediate locality of the tumour the retina is detached, and this detachment increases with the advance of the disease.

Treatment of Glioma.—Excise the eye as soon as the disease is discovered, and, should the two eyes be affected, both should be excised, provided the sight has been already destroyed. The removal of the two eyes in such a case would afford the only chance of recovery, whilst at the same time it would save the child much ultimate suffering. The writer has on many occasions removed the second eye for the sole purpose of procuring some temporary relief from the excessive pain induced by the over-distended globe, and when there has not been the slightest prospect of arresting the

disease. In each case the operation gave immediate and perfect relief. Even if the disease should recur rapidly in the orbit, the child is greatly benefited by having had the eye removed, as the growth of the tumour in the orbit is comparatively painless when the resistance caused by the eye has been taken away. GEORGE LAWSON.

ORBITAL ANEURISM.—*Symptoms.*

If the term 'orbital aneurism' were strictly interpreted so as to embrace instances of circumscribed and diffused aneurisms, arterio-venous communications, and aneurism by anastomosis affecting vessels only within the limits of the orbital cavity, the space necessary for their description would be very small. There are on record very few genuine cases of aneurisms of vessels within the orbit. But in the immediate neighbourhood of the orbit there are large blood-vessels, whose morbid conditions affect the circulation within the orbit and the eye, and give rise to aneurismal symptoms that find here a characteristic outward and visible expression, by which they become cognisable to the clinical observer, and arouse the serious solicitude of the patient.

Aneurismal affections and morbid conditions of blood-vessels within the orbit, within the cranial cavity immediately behind the orbit, and possibly in the pterygoid and sphenomaxillary fossæ, give rise to symptoms essentially similar. The common features, variously combined and modified in different cases, are protrusion of the globe or exophthalmos; pulsation of the protruding globe, palpable to the touch and often visible to the eye; a soft pulsating tumour at some point of the orbital margin, usually above the eye, beneath the inner part of the orbital arch, but occasionally at the outer side, sometimes below the eye at the lower and inner angle; bruit and noises in the head; distended veins on the conjunctiva and on the lids and forehead; chemosis; obliteration of the hollow beneath the orbital arch; pain; paralysis of orbital muscles and iris; and cessation or lessening of the bruit and noises in the head, recession of the globe, and diminution of the swelling and abolition of pulsation by pressure on the corresponding carotid artery. The most characteristic symptoms are the presence of a pulsating tumour at the orbital margin and pulsation of the protruding eyeball. Hence, the terms 'pulsating tumour of the orbit,' 'pulsating exophthalmos,' and 'vascular protrusion of the eyeball,' are sometimes employed to describe cases in which these phenomena

are conspicuous. The advantage of these terms is that they do not express any theory of causation; the disadvantage is that they are not individually and universally applicable to all cases in which the diagnosis of aneurism may fairly be made. Pulsation of the eyeball, vascular protrusion of the globe, and a pulsating tumour may each in their turn be absent, without contra-indicating the diagnosis of 'orbital' or 'intra-orbital aneurism,' a phrase in itself open to objection for the expression of a group of aneurismal symptoms, whose cause lies far more frequently behind the orbit than in it.

It will be as well to premise that cases of orbital aneurism sometimes arise spontaneously, and sometimes are the direct result of injury—in other words, are divisible into two groups, the idiopathic and traumatic.

Pathology.—There have been at least fourteen post-mortem examinations of cases of so-called orbital aneurism, with the following results:—

1. In one bilateral case (Guthrie's), an aneurism of the ophthalmic artery was found in each orbit.

2. In three idiopathic cases (Baron, Gendrin, Nunneley), there was a ruptured aneurism in the cavernous sinus.

3. In four traumatic cases (Nélaton (2), Herschfeld, Schlaefke), there were arterio-venous communications between the carotid and the cavernous sinus.

4. In four cases—one traumatic, three idiopathic (Bowman and Hulke, Aubry, Ettingen, Morton), there were blocked orbital veins and cranial sinuses.

5. In one idiopathic case (Nunneley), there was an old aneurism of the ophthalmic artery within the cavernous sinus.

6. In one idiopathic case (Wecker and Richet), there were dilatation and atheroma of the carotid.

The two latter observations are not satisfactory, and the first leaves much to be desired. The fourth or venous group is important, and may be said to require support by future observers, who will work with the knowledge that arterio-venous communications are frequent causes of the symptoms of orbital aneurism, but may be readily overlooked at post-mortem examinations superficially conducted, and so completely explain the aneurismal symptoms both in idiopathic and traumatic cases; and that thorough examination of both carotids and both internal maxillaries should be made if all scepticism as to the absence of arterial lesion is to be placed out of court.

Post-mortem examinations have further proved that—

(a) Thrombosis of the cavernous sinus and ophthalmic vein may be present without occasioning the essential symptoms of intra-orbital aneurism. Exophthalmos, cedema of the orbit, hyperæmia, photophobia, dilated immovable pupil, paralysis of the muscles of the eye, and diminution of vision are the evidences of this condition.

(b) Aneurism of the internal carotid in the cavernous sinus may be present without giving rise to the essential symptoms of intra-orbital aneurism. The same remark will probably be found applicable to aneurisms of the ophthalmic artery at its origin from the internal carotid. The orbital symptoms, noted in cases of aneurism of the internal carotid in the cavernous sinus, have been sometimes only symptoms due to pressure on the nerves, especially the third, fourth, and fifth, such as ptosis, dilated and fixed pupils, impaired or uncertain movements of the eyeball, diplopia, defective sight; and sometimes superadded to these, symptoms due to obstruction to the return of venous blood, cedema of the lids and conjunctiva, hazy and ulcerated cornea, and injection of the sclerotic and conjunctiva. The other symptoms have been violent pains in the head and at the back of the orbit, continual headache or heaviness of the head, unrelieved by treatment, and singing or other noises in the head.

(c) The cavernous sinus may be obliterated without giving rise to the essential symptoms of intra-orbital aneurism.

With regard to the nature of the reported cases—more than 100 in number—the following statements may be made:—

1. Beyond question, the great majority of the traumatic cases have been instances of endocranial arterio-venous communications, due to wound or rupture of the internal carotid artery in the cavernous sinus.

2. Beyond question, the great majority of the idiopathic cases have been instances of endocranial arterio-venous communications, due to rupture of an aneurism of the carotid or of an atheromatous carotid, in the cavernous sinus.

3. The occurrence of a circumscribed aneurism of the ophthalmic artery, or one of its branches, as a cause of the same symptoms as were exhibited in the cases of arterio-venous communication, rests, at present, solely on the laconic report of Guthrie, who gave no account of the condition of the cavernous sinuses and internal carotid arteries. Moreover, aneurism of the ophthalmic artery in the orbit is a very rare

affection. Small aneurisms are occasionally found, with the ophthalmoscope, on the branches of the arteria centralis retinæ.

4. Diffused aneurisms of the ophthalmic artery have not been shown to have given rise to the symptoms of 'orbital aneurism.' In 1859 M. Demarquay divided the cases of intra-orbital aneurism into two categories—the traumatic and the idiopathic. The traumatic he regarded as dependent upon a rupture of the ophthalmic artery, followed by an effusion of blood and the formation of a diffuse aneurism, which he called a 'primitive diffuse aneurism'; whilst in the idiopathic cases he supposed that there existed, first of all, a circumscribed aneurism of the ophthalmic artery, which was suddenly ruptured and became diffuse at the time of the commencement of the symptoms, and this form of aneurism he called 'consecutive diffuse aneurism.' M. Demarquay's views were adopted by some authorities, but they have not yet been shown to be even partially true. In no one case have the symptoms of intra-orbital aneurism been proved to be due to a tearing across of the ophthalmic artery, at or near the optic foramen.

A few cases of pulsating sarcoma have crept into the lists of cases. Freer's case was one of fungus hæmatodes. Critchett's was a pulsating sarcoma, and so in all probability was Szokalski's case. Van Buren's sarcoma case is included in some lists.

The *Differential Diagnosis* of the various morbid conditions of blood-vessels within and behind the orbit, and of the affections which may be mistaken for them, will best be established by a summary of the distinctive features of each.

1. *Traumatic arterio-venous communications between the Carotid Artery and Cavernous Sinus* will be preceded by the history of an efficient lesion, such as a bullet wound or shot wound, a punctured wound, or a blow or fall sufficient to occasion a fracture of the base of the skull. Occasionally, the communication will be on the side opposite to the seat of injury in the orbit; usually, the two will correspond. At first, the aneurismal symptoms may be masked by the general symptoms of injury to the head. As a general rule, they are fully developed within nine months of the accident preceding the affection. More than half the cases exhibited all the symptoms within two months. Some of the cases were not seen till a much later period, but, from the history, it is clear that all the symptoms were well established a few weeks after the

injury. In one or two cases only was there an interval of years. The primary symptoms present some variations. In some, a blowing, roaring, or singing noise, or beating in the head, is stated to have been heard either immediately or soon after the injury. In a few, congestion of the conjunctiva and chemosis, with or without loss of power in the ocular muscles and inaction of the pupil, preceded exophthalmos, pulsation, and bruit; so that in two or three cases the patients seemed to be affected with simple conjunctivitis. Exophthalmos is said to have preceded the pulsation and bruit in about half the cases, and was noticed within the first six weeks in a similar proportion.

Doubtless, the interval between the infliction of the injury and the occurrence of the typical symptoms is due to blocking up of the aperture in the artery by coagulum, or pressure on the cavernous sinus and ophthalmic vein by coagulum, which subsequently undergoes absorption or disintegration. Hence, in the early stage, the only symptoms may be some swelling and redness of the conjunctiva, with slight proptosis, due to obstruction of the venous current; but, as soon as the aperture of communication has become clear, noises in the head, bruit, and pulsation in the eyeball will declare themselves. In some cases, a partial rupture may occur and become complete after a variable interval, or weakening of the coats by injury may lay the foundation for ordinary aneurism. As soon as the arterial blood finds its way freely into the cavernous sinus, it will be propelled into the ophthalmic vein, or veins superior and inferior and their tributaries, giving rise to pulsation of the eyeball and the development of a pulsating tumour or tumours at the margin of the orbit, soft, lobulated, compressible and repressible, obliterating the hollow beneath the arch. Pulsation of the eyeball may disappear when the pulsating tumour has developed itself. Congestion of conjunctiva and chemosis will tend to increase. A large pad of infiltrated mucous membrane will project between the lids.

The pulsating tumour will require time for its development, and before the dilated ophthalmic vein or veins become evident at the margin of the orbit, the pulsation may be communicated to the eyeball, so that pulsating exophthalmos will take precedence of the appearance of a pulsating tumour or tumours. In process of time, a tumour will commonly appear at

the inner third of the orbital margin, and the distension of the veins may gradually extend to the tributaries of the main trunk, thus reaching the forehead, the bridge of the nose, and the inner angle of the opposite orbit as well as the lower eyelid. The constant pulsations of the ophthalmic vein may wear a furrow in the bone. With the ophthalmoscope, prominence of the disc, hæmorrhagic spots, and dilated and pulsating retinal veins will be observable. A vibratory thrill in the pulsating veins is a frequent but not constant phenomenon. The bruit is often peculiar and distinctive. It is a continuous bruit, with *redoublement* or reinforcements during the arterial pulse; and, added to this, is a high, plaintive, whistling note, caused probably by the rushing of the arterial blood through a small hole in the carotid, designated by French authors the *bruit de piaulement* or *miaulement*, from its likeness to the mewings of a cat, and audible, perhaps, only in front of the eye over the course of the dilated ophthalmic vein. If the pulsating tumour or tumours are tapped or punctured, arterial blood will issue.

Nerve-lesions may be due either to the same injury by which the artery was wounded or to pressure on the nerves by effused blood and blood-clot. The optic nerve may be torn in a fracture of the base, or the sixth nerve divided by the foreign body which causes a wound of the carotid. Impairment of vision, at a later period, may result from alteration in the circulation or loss of transparency of the media. Ptosis, dilated pupil, and external strabismus from pressure on the third nerve, are not uncommon.

In some cases, the opposite orbit and eye become affected by the passage of arterial blood, from the cavernous sinus on one side through the circular sinus into the opposite cavernous sinus and ophthalmic vein. The arterial blood may also find its way through the emissary veins into the pterygoid plexus, and so, the writer believes, into the temporal veins and into veins on the floor of the orbit, which pass through the spheno-maxillary fissure. When one channel is blocked up another is opened. This explains the recurrence of the disease, in some cases, on the side opposite the seat of injury after subsidence or cure by ligation on one side, and the recurrence on the outer side of the orbit after cure on the inner. A long-neglected case of aneurismal varix may attain a wide development.

2. *Idiopathic arterio-venous communications between the Internal Carotid and*

Cavernous Sinus occur usually quite suddenly, from the rupture of an aneurism of the internal carotid or rupture of a diseased internal carotid, as it lies in the cavernous sinus. In the majority of cases, the disease commenced with pain or noise in the head, or some peculiar feeling on the affected side; in a few gradually, with or without attacks of premonitory pain. Five cases occurred during pregnancy in women who had borne several children. In all the attack occurred quite suddenly, with violent pain and noise in the head variously compared to a 'sudden snap,' the 'cracking of a whip,' 'the report of a pistol overhead,' 'a blowing noise,' and 'a steam hammer;' whilst in six other females not pregnant (three being over sixty years of age), in whom the attack was equally sudden, the several sensations experienced were described as 'something appearing to give way,' with or without a crack like that of a gun, 'a kind of crowding feeling,' 'a strong buzzing,' 'a violent pain in the eye or temple,' and 'something queer in the head.' Two of these patients were aroused from sleep by the pain and noise, in two the affection began as they were getting up as usual in the morning, and the others as they were pursuing some ordinary occupation, such as washing, taking off shoes, rubbing in a liniment, returning from a drive, and sitting down to work. One woman, during an effort of childbirth, felt an 'unusual rattling in the eye,' and perceived that the eye was driven from the orbit; whilst another attributed the affection to an effort made during her last confinement, five years previously. One man felt a deep-seated pain in the eye and singing in the ear, as he was aroused from sleep. Another perceived one morning, after a fit of coughing and without any premonitory symptoms, that the eye was projecting from the orbit.

After the pain and noises, the next symptoms to appear are generally exophthalmos and swelling of the lids and conjunctiva. In extreme cases, the eye may be almost extruded from the orbit. Paralysis of orbital muscles, pulsation of the eyeball, the development of pulsating tumours out of the ophthalmic vein and its branches at the orbital margin, with thrill and the characteristic bruit, dimness and sometimes loss of sight, dilated and fixed pupil, eversion of the lower lid and increase of the conjunctival pad (forming a bright-red tumour projecting between the distended eyelids), pain, often constant and acute, at the bottom of the orbit, and noises

in the head, will soon be superadded to the earlier symptoms. Arterial blood would issue if the pulsating tumours were punctured. As in the traumatic series, the affection may spread to the opposite eye, or commence in the opposite eye after cessation or cure on the same side by ligature of the carotid.

3. *Circumscribed aneurism of the Ophthalmic Artery* would probably, as in Guthrie's case; cause pulsating exophthalmos without a pulsating tumour appearing at the orbital margin, and the bruit might be distinctly intermittent.

4. *Traumatic rupture of the Ophthalmic Artery* in the orbit would, in all probability, be accompanied by tearing across of the optic nerve, and be followed by protrusion of the eyeball and immediate and irreparable loss of vision. There are no facts to guide us in regard to rupture of a true aneurism of the ophthalmic artery in the orbit.

5. The distinctive features of *Aneurismal Varix* within the orbit remain to be determined. A single case of varicose aneurism of vessels within the orbit has been reported.

6. *Obstructed Cranial Sinuses and Orbital Veins* have not yielded symptoms sufficiently distinctive from aneurismal varix of the ophthalmic vein, due to wound or rupture of the internal carotid, to be distinguished. There is one probable means of diagnosis—viz. puncture of the pulsating and dilated ophthalmic vein. In aneurismal varix, arterial blood would issue; in blocked sinuses, &c., venous blood might be expected to appear. Puncture, however, does not exercise a beneficial influence on the part.

7. *Vascular Tumours of the Orbit* are of various kinds, all shading into each other. There are erectile tumours, consisting either of capillary vessels or of a cellular, reticulated, and spongy tissue, containing either arterial or venous blood, and often surrounded by a capsule of condensed connective tissue. These cavernous tumours have neither pulsation nor bruit. Yet they dovetail into the cases of pulsatile arterial nævus, in which a soufflé existed with doubtful pulsation. There appear to be cases also of pulsatile venous nævus. Then, there are venous or varicose tumours formed of dilatations of the ophthalmic vein or its branches, owing to some obstruction to the return of venous blood. If formed by the ophthalmic vein, they will be prominent at the upper and inner part of the orbit, and yield similar sensations to those afforded by the pulsating tumours found in cases

of intra-orbital aneurism, in so far as this, that they will be peculiarly compressible and repressible, but will have neither bruit, pulsation, nor thrill. They will increase in size in expiration and stooping, and diminish in inspiration and the erect posture. Pressure on the internal jugular vein should cause them to swell. These tumours may originate after injury.

8. The true '*Cirroid Aneurism*' or '*Aneurism by Anastomosis*' is composed of vessels elongated, varicose and tortuous, very thin-walled, and more like veins than arteries in structure. The dilated vessels collected together form pulsatile thrilling tumours, soft and compressible. The vessels are usually described as arteries; but it is admitted that the dilatation may invade the arterioles and capillaries, and even spread to the veins, and there can be little doubt that many of the large pouched and pulsating vessels of a cirroid aneurism or aneurism by anastomosis are in reality pulsating veins. This being so, it is difficult, if not impossible, to point out any marked external differences between aneurism by anastomosis in its extreme development and aneurismal varix, and it is no wonder that Travers, Dalrymple, and others adopted this view of intra-orbital aneurism. The chief difference consists in the fact that in one case there is no arterio-venous communication, and that in the other this communication exists. No proof has been afforded as yet that 'aneurism by anastomosis' in its extreme development occurs in the orbit as a separate affection. It may spread to the orbit from the face or head; but further observations of a much more precise nature than those of Dr. Morton will have to be made to establish the affection in the orbit. On the other hand, arterio-venous aneurisms rest on so immovable a pathological basis, and attain so wide a development in severe cases, that this diagnosis naturally occurs to the mind in all cases where pulsating veins are found. In Brainard's traumatic case there was a loud blowing sound over the orbit and more or less over the head, the veins of the face were prominent, the arteries of the head and neck pulsated with unnatural force, thrill was heard over the whole head, there was an elastic and pulsating swelling at the upper and inner part of the orbit and root of the nose, and the small vessels of the forehead and side of the nose pulsated with a peculiar thrill. If aneurismal varix holds good for this case, it holds good for the severe cases of orbital aneurism which have been reported as ex-

amples of 'aneurism by anastomosis,' and the writer is inclined to believe that other cases of cirroid aneurism following an injury really belonged to aneurismal varix.

9. *Pulsating Sarcoma* of the orbit (previously described as encephaloid cancer) has many features in common with arterio-venous communications, or idiopathic and traumatic aneurismal varix. Loss of vision, exophthalmos, pulsation, noise in the head, and bruit ceasing when the carotid of the corresponding side is compressed, are symptoms of sarcoma and symptoms of aneurism. Its onset is often obscure, and the case will be still more obscure if the orbital tumour exists alone and if its development has followed an injury. Moreover, the sarcomatous tumour, projecting outwardly, may yield a soft, semi-fluctuating sensation, peculiarly liable to deceive even the experienced practitioner. In M. Lenoir's case, the carotid artery was tied, under the impression that the affection was aneurismal. The disease had followed a fall on the back of the head, and the only symptoms of differential value were the light whispering character of the bruit, the irreducibility of the tumour, and its extension towards the temporal fossa. Pulsation may be present without bruit, and the diagnosis will then be more obvious. In Mr. Nunneley's case of 'cancer of the orbit' the carotid artery was tied, and checked the progress of the disease. Here the diagnosis was rendered probable by the existence of multiple tumours, and by the continuation of the orbital tumour into the zygomatic fossa. By attention to this latter point, the character of the bruit, &c., the writer was able to diagnose malignant disease in a case in which it had been proposed to tie the carotid artery for suspected aneurism, and to ensure the abandonment of the proposal. Ligature of the carotid has several times been practised by American surgeons. In one or two cases a fatal result occurred; in others a combination of ligature with extirpation of the growth proved successful. Ligature checks for a short time the progress of the disease, but it is only to be advised in exceptional cases.

10. A *Meningocele* of small size may project at the internal angle of the orbit and be mistaken for a nevus or erectile tumour. This happened in M. Guersant's case, which was seen by many Fellows of the Surgical Society of Paris, who agreed in recommending treatment by thread setons. Cerebral symptoms supervened, and the child soon died. It was found, at the post-mortem examination, that the tumour was composed of a small portion of brain-substance

covered by the membranes of the brain, which had passed through the fronto-ethmoidal suture, and appeared at the inner angle of the orbit.

11. In Graves's disease, pulsation of the prominent eyeballs is absent. Derangement of the sympathetic system, or a morbid state of the lenticular ganglion, has no known connection with the production of symptoms resembling those of aneurismal varix of the ophthalmic vein.

12. The distinctive features of thrombosis of the orbital veins, aneurism of the carotid in the cavernous sinus, and aneurism of the ophthalmic artery before it enters the orbit, may be gathered from what has been stated above under the head of pathology.

Treatment.—In a small proportion of both traumatic and idiopathic cases, the symptoms of orbital aneurism have subsided in the course of weeks, months, or years by simple means, such as attention to diet and abstinence from stimulants, application of cold, exhibition of drugs like belladonna, veratrum viride, ergot, and digitalis, and mechanical compression of the pulsating tumour. To oppose the expectant treatment, we have Nélaton's case dying from hæmorrhage from the nose only, mechanical treatment having been employed; and Scott's case, saved from a similar fate by prompt ligation of the carotid. To these we must add several cases, in which the symptoms were aggravated after the lapse of months or years. The surgical means of treatment at our disposal are local compression of the tumour, digital and instrumental compression of the common carotid, galvano-puncture, subcutaneous injection of ergotine, injection of coagulating fluids into the pulsating veins, ligation of vessels within the orbit, with or without removal of the pulsating mass, and ligation of the carotid artery or arteries.

Local compression produced some benefit in three cases, and was either useless, too painful, or injurious by increasing the chemosis and congestion, in seven others.

Instrumental compression has failed in several cases. Glascott, however, in 1883, related a successful instance in a traumatic case. A man, forty-two, fell down an open hatchway. The night after the accident he noticed a whizzing noise in his head, which continued. A month after the accident his left eye began to protrude. When first seen, the upper lid was swollen, conjunctiva chemosed, and vision very much reduced. The ocular and conjunctival veins were enormously distended and varicose, and the

retinal veins were enlarged and tortuous. At the inner superior angle of the orbit a large vessel was seen pulsating. On applying a stethoscope, a quarter of an inch above the supra-orbital notch, a loud blowing murmur was audible, synchronous with the cardiac systole, and was not continuous. Patient was put on ten grains of pot. iodide, and compression of the left carotid was maintained by the patient with a compressor, made of a wooden knitting needle with its head protected by a firm pad. Compression was kept up by the patient for two minutes at a time, every quarter of an hour. Compression, begun on September 30, was kept up till December 21. The large vessel at the superior inner angle had ceased to pulsate. No pulsation was detected anywhere in the orbit, nor any bruit. There was old clot at the bottom of the anterior chamber, and there was no perception of light.

Digital compression of the common carotid was first practised by Gioppi. It failed in ten traumatic cases, and cured three out of six idiopathic cases. It may either be continuous or intermittent, and it is worth noticing that in the three successful cases (Gioppi, Scaramuzza, and Galezowski), as well as in Glascott's case, just related, it was only practised for a short period in the twenty-four hours, and not for many minutes at a time. In Gioppi's case, as compression caused faintness, it was only employed, for a minute or two at a time, by the convalescent patients in the ward, the patient herself, and the pupils. Pulsation and noises ceased at the end of the fourth day. In Scaramuzza's case digital compression, employed very cautiously on account of aortic disease, was practised for not more than five or six turns, the total period of compression being only seven hours twenty minutes. The eye had then entirely re-entered the orbit, and pulsation had ceased. In M. Galezowski's case, compression was practised every two or three days for fifteen or twenty minutes, afterwards increased to forty-five or sixty minutes daily. Marked relief followed each sitting, and, at the end of a month, the movements of the globe had returned, the eyelid was raised, and the chemosis was gone. An interruption of the treatment for about a fortnight took place; then it was recommenced, and continued for more than two months every two or three days. A month later, the protrusion had almost entirely disappeared, the patient heard no bruit, and none could be heard on auscultation over the cranium.

Digital compression of the carotid should not be practised, by any one person, for more than ten or fifteen minutes at a time without relief. It is by no means easy of efficient application by inexperienced assistants, but it is a valuable method of treatment, free from danger when applied with due precautions, capable of occasionally effecting a cure, especially in idiopathic cases, and serves as a valuable preparation for ligature by establishing anastomosing channels, and preventing disturbance of the cerebral functions subsequently to ligature.

Galvano-puncture is not well suited for application to a thin-walled aneurismal varix of the ophthalmic vein. It has twice failed in a traumatic case. M. Pétrequin's patient died after ligature and subsequent galvano-puncture, but whether from the former or latter method, or the combination of the two, is not clear.

Injection of ergotine subcutaneously was practised in the case of Schiess-Gemuseus and Socin, and produced nausea, vomiting, cedema, and increase of the tumour. There are no rational grounds for expecting success from this procedure.

Injection of a coagulating fluid into the pulsating tumour has been practised four times. In two traumatic cases (Bourguet and Desormeaux) a solution of the perchloride of iron was used and effected a cure, vision being restored. In Brainard's case, the lactate of iron effected a cure after the failure of ligature, but the eye was lost. Brainard had previously tried the effects of the lactate of iron in solution on a dog without ill effect, and he had also used it on the human subject, injecting it into the veins at the bend of the elbow. Each of the veins into which it was thrown was obliterated after a time, and converted into a fibrous cord. He considers that, while the perchloride of iron is a foreign substance causing coagulation of the blood, and is apt to be followed by gangrene and suppuration, lactate of iron is composed of elements which are natural elements of the blood, and acts by gradually causing thickening of the coats of the veins, converting them into fibrous cords and thus obstructing the circulation. In the writer's case, the quantity of perchloride injected (5 drops) proved to be insufficient to effect complete coagulation.

Injection of coagulating fluids in arterio-venous aneurism stands on a different footing from injection of a nævus, as the blood-current in the veins is reversed. It is only adapted for aneurismal varix of the ophthalmic vein and its branches, outside

the orbit. It is more painful than ligature and probably involves more risk to vision, as it may set up inflammatory mischief in the loose areolar tissue round the veins, which may spread to the cornea. It may also effect so much coagulation as to interfere with the requisite supply of blood for the maintenance of the ocular tissues. When injection is practised, pressure on the carotid should be maintained during the operation.

Taking account of those cases only of which the writer knows some of the particulars, *ligature of the common carotid* has been practised 56 times in 54 cases, the right carotid having been tied 21 times and the left carotid 33 times. In two cases the side is not stated. Of the 54 cases, 21 were idiopathic and 32 traumatic—the nature of the other case not being known to the writer. Of the 21 idiopathic cases in which ligature was practised, 12 were affected on the right side and 9 on the left; 4 died and 17 recovered. Two of the patients who died were females advanced in years, and both had atheromatous arteries. One, aged sixty-five, died on the sixteenth day from secondary hæmorrhage and cerebral disturbance; the other, aged sixty-three, died in fifty-two hours from cerebral causes only. A third (Critchett's) case was of a malignant nature, and the patient succumbed, some months after the operation, from repeated hæmorrhages from the orbit. The fourth patient, a female, aged only twenty-three, operated on by Dr. Morton, died suddenly, the day after the operation, from inflammation at the base of the brain. Of the 17 patients who recovered, 13 were cured of the aneurismal affection, vision being restored in 9, lost or not regained in 3, and not mentioned in the others. In 3 partial benefit resulted, vision being lost in 1, impaired in 1, and not mentioned in the other. In 1 (Frothingham's) the aneurismal affection subsided for a time. Pulsation returned in fourteen days. Three years later the disease was again urgent. The eyeball was enucleated and the tumour removed, and the patient recovered.

Of the 32 traumatic cases 5 died and 27 recovered. The ages of the patients who died were respectively seventeen, twenty-two, forty, thirty-three, and forty-two. One of the five was subjected to galvano-puncture subsequently to ligature, and the cause of death is not stated. In 3 cases the cause of death appears to have been pyæmia, 1 recovering from the operation, but returning to the hospital and dying at the end of three months. The

fifth patient (Dr. Morton's) died rather suddenly, from serous apoplexy, during the night after the ligature. Of the 27 patients who recovered after ligature of one carotid, only 17 were cured of the aneurismal affection of the orbit, 1 subsequently to injection, vision being lost or not regained in 6, and the bruit being noted as persisting in 4. In 8 of the 17 the cure was in all respects complete. In 1 the common and external carotid arteries were tied on the side affected. In 5 the operation was unsuccessful; 2 were subsequently cured by ligature of the opposite carotid, and 1 by injection of lactate of iron. In 5 partial benefit resulted, the symptoms being diminished but not removed in 3, and being removed for a time only in the others. In Velpeau's case, the symptoms were removed altogether on the left side but returned on the right. In Knapp's case, ligatured by Dr. Sands, the symptoms returned; the exophthalmos increased, the cornea sloughed, and the eye was lost by panophthalmia. The eye was enucleated and a large pulsating ophthalmic vessel (evidently the vein) ligatured at the apex of the orbit. The patient recovered. One case (Flatten's), whose nature is not known to the writer, was cured.

Taking the two sets of cases together, we have a total of 54 cases. Out of this number there were 8 deaths, for one death was unconnected with the operation, 5 failures to cure the disease, 9 partial successes and temporary removal of the symptoms. Of the 5 cases in which the operation failed, 2 were cured by ligature of the opposite carotid and 1 by injection. Of the 31 cases cured, vision was restored in 20, lost or not regained in 9. The bruit persisted certainly in 4, and probably in others not examined with the stethoscope.

The two cases in which both carotids were tied occurred in America. In one case, the interval between the operations on the two arteries was thirty days, in the other fourteen months. Vision appears to have been improved in the former case, but it had been lost and was not regained in the other.

Ligature of the common carotid is at present the most successful and satisfactory means of treating orbital aneurism. It should not be practised on patients advanced in years, or on those with heart-disease or evident atheromatous degeneration of arteries. The two cases operated on over sixty years of age succumbed, and if we deduct these as well as Pétrequin's case, in which the subsequent galvano-puncture may have been the real cause of death, there were 5

deaths in 54 cases, or rather 56 operations. One of the 5 deaths did not take place till three months after operation, and can scarcely be regarded as directly caused by it. Two of Morton's cases died suddenly within twenty-four hours, and were probably not in a fit state for operation, having already some inflammatory affection at the base of the brain. If these last three cases are included, the death rate would be about nine per cent.; if excluded, it would be under four per cent. The percentage of absolutely successful cases or cures would be about fifty-five.

Return of the symptoms after ligature may take place in three different ways. In cases of arterio-venous communication, the symptoms may return on the same side from want or deficiency of coagulation of the blood in the ophthalmic vein, carotid artery, and cavernous sinus, or clot may form temporarily and be washed away. Secondly, the symptoms may return either on the opposite side or in the outer part of the same orbit, after being cured on the inner side. Obliteration of the ophthalmic vein may have occurred on the side originally affected, but, the arterio-venous opening still remaining patent, the arterial blood is either pumped into the circular sinus and the cavernous sinus and ophthalmic vein on the other side, or through the emissary veins into the pterygoid plexus, and so may reach the same orbit again through the sphenomaxillary fissure. If there are two ophthalmic veins, one may be obliterated and the other become correspondingly enlarged, or both may expand together. Thirdly, in cases of true aneurism, the affection, which seems to have been a return on the opposite side, may be in reality the formation of an aneurism *de novo*. Although ligature of the carotid seems to offer the best chance of recovering useful vision, when vision is impaired or threatened, it is by no means an infallible remedy. If vision is lost or nearly lost before operation, it will rarely be regained; if only impaired it will probably improve, but there are one or two cases in which sight was lost subsequently to ligature.

The causes of loss of vision in cases of orbital aneurism both before and after treatment deserve attention. In some traumatic cases, the optic nerve may be torn across at the time of the accident; in some idiopathic cases, the damage to its structure may occur from pressure of a circumscribed aneurism or pressure of blood-clot when an aneurism is ruptured. Pressure on the ophthalmic nerve may occasion, directly or

indirectly, ulceration of the cornea. Vision has been lost in cases treated simply, treated by digital compression, treated by injection, and treated by ligature. The cornea has grown hazy after ligature and recovered itself; it has ulcerated after ligature, and the eyeball has atrophied more than once; it has ulcerated and healed before ligature, and it has ulcerated before ligature and healed afterwards. Vision, almost lost before injection of perchloride of iron, has been regained afterwards; injection has also been followed by ulceration of cornea, severe inflammation of the eye, loss of the humours and collapse of the globe. In all cases, vision rests on a precarious foundation, and it is impossible to predict positively whether the treatment recommended will succeed in preserving or restoring it in any particular case. Delay in treatment certainly endangers vision. The altered conditions of nutrition render the preservation of transparency in the media and of the integrity of the retina precarious, whilst treatment involves the possibility of excessive coagulation in the vessels, and interferes with a due supply of blood. On the whole, the evidence appears to be in favour of early resort to ligature, as affording the best prospect of restoration or preservation of sight. In case of failure of ligature on one side, the question of ligaturing the opposite carotid will present itself for consideration, and may be answered by first ascertaining the effect of digital compression of the vessel. Ligature of the opposite carotid will also have to be compared with other available methods, such as coagulating injections.

Ligature of the aneurismal ophthalmic vein at the apex of the orbit might be feasible and successful, in selected cases.

Ligature of pulsating vessels in the orbit has been attempted or practised on three occasions. In 1860 M. Passavant, diagnosing a traumatic aneurism of the lacrymal artery in a girl of nine, who had been wounded by a knitting-needle thrown at her in a rage by her sister, attempted to reach and tie the vessel by dissecting the soft parts from the external wall of the orbit, and resecting the bones sufficiently to allow the finger to penetrate behind the globe. At the apex of the orbit, very deeply and on the inner side of the optic nerve, the finger encountered the pulsations of an aneurismal pouch, but all attempts to tie it were vain. The child remained after the operation in the same state as before.

Arterio-venous aneurisms of vessels within the orbit are almost unknown. In

1875 Mr. Lansdown of Bristol reported 'a case of varicose aneurism of the left orbit cured by ligature of the diseased vessels.' A few cases have some claims to be regarded as instances of 'aneurism by anastomosis.' Noyes, in an idiopathic case occurring in 1881, tied the angular artery (?) and exposed a protruding pulsating vessel at the inner and lower side of the orbit. The latter was then cautiously dissected up and traced into the cavity of the orbit, until it reached the groove for the infra-orbital nerve, where it dipped down. A ligature was put about this end and the vessel excised. It proved to be a vein and was larger than a crow-quill. In eighteen days both ligatures came away. In fifty days the patient was discharged. Pulsation ceased, and the eye returned to its place. Three other cases, in which the eye and the pulsating vessels have been enucleated, were operated on by Frothingham, Knapp, and Morton respectively.

WALTER RIVINGTON.

ORCHITIS. See **TESTIS**, Diseases of the.

OS CALCIS, Excision of the.—It is not uncommon to meet with cases in which the os calcis alone of the tarsal bones is the seat of degenerative disease; and when any large part of its central tissue is softened, or a considerable portion of its surface is carious, the bone may with great advantage be dissected out from its connections with the rest of the tarsus, and a most useful foot be left.

Operation.—The best method of removing the os calcis is that recommended by Mr. Holmes. An incision is made on a level with the upper border of the bone, commencing at the inner edge of the tendo Achillis, and passing forwards to a point a little in front of the calcaneo-cuboid joint, which lies midway between the outer malleolus and the base of the fifth metatarsal bone. The incision should be made down to the bone, and divide the tendo Achillis. Another incision is then to be drawn across the sole at a right angle to the first, and at a point corresponding to the calcaneo-cuboid joint; it should stop short of the outer border of the grooved or internal surface of the os calcis, so as to avoid the posterior tibial vessels. The flap thus formed is dissected up and the calcaneo-cuboid joint freely opened; then the connections of the calcaneum with the astragalus are divided. The bone should next be levered out of its bed to some extent with an elevator, and grasped with the lion-forceps, by which it

is to be turned aside, so that the soft part can be carefully cleared from its inner side. Any remaining ligamentous attachments being now divided, the bone can be pulled away.

The operation will be much facilitated by the use of an Esmarch's bandage, which enables the position of the joints to be more easily seen. The flaps are to be brought together with sutures, a drainage-tube inserted, and the limb placed upon a splint, with the foot at a right angle to the leg. The gap left by the removal of the bone fills up with dense fibrous tissue. The tendo Achillis takes a fresh attachment, and as a rule a perfectly useful foot results, the only deformity in which is a slight elevation of the heel.

Many surgeons prefer to dispense with the sole incision altogether, and prolong the horizontal cut on the inner side of the foot to a point corresponding with the calcaneo-cuboid articulation on the outer side. The advantage of this method is that the scar is not exposed to pressure.

Another method of removing the os calcis is that of turning back a flap from the heel, such as is made in Syme's amputation, the incision running from the tip of the outer malleolus to a corresponding point on the inner side of the foot; the joints are then opened and the bone dissected out. This, however, is a much less convenient plan than that first described.

The subperiosteal method is tedious, and does not seem to give better results than the ordinary operation.

OSMIDROSIS. *See* HYPERIDROSIS.

OSTEO-ANEURISM.—It is doubtful if this term ought still to be preserved; for all the cases of pulsatile tumours of bone which have been recorded of recent years, since the general use of the microscope, have proved, when this method of investigation has been adopted, to be central sarcomata. A large proportion of the myeloid and round-celled sarcomata, growing in the cancellous tissue of bone, pulsate distinctly, and, before the microscope was employed for the examination of these tumours, were often described as osteo-aneurisms, on account of their pulsation and the apparent absence of anything more solid than blood-clot. But in the outlying parts of such tumours, new-growth, of the sarcomatous type, has, of recent years, always been found.

Under **TUMOURS OF BONE** a clinical description of these endosteal growths is given, to which the reader is referred for further information. Their pulsation seems, in most cases, to be due to the large number of new and dilated vessels which they contain. In some of the myeloid sarcomata numerous cystic cavities are found, filled with blood in different degrees of consistence, into which the enlarged vessels probably open; but the growth is so soft and diffuent that an accurate examination of the centre can very rarely be undertaken. The more solid tissue in the outlying and peripheral parts of the growth is that which is generally examined, to demonstrate the nature of the tumour; and this examination, as stated above, has almost invariably proved that the growth is one of the sarcomata, most frequently the myeloid or round-celled.

A vascular tumour has also been described as occurring in the flat bones, such as those of the skull in young children, resembling in its general structure the arterial erectile growth that is occasionally seen in the soft parts of the face and scalp.

H. H. CLUTTON.

OSTEO-ARTHRITIS.—A chronic disease of the joints, occurring usually in persons past maturity, and giving rise to extensive changes in the shape and texture of the articular tissues, with corresponding interference with function.

The striking features of this disease are the altered shape of the joint surfaces, which are worn away in some parts and irregularly nodulated in others; the softening and destruction of ligaments, allowing displacement of the bones; the loud and easily felt crepitus on movement; and the progressive loss of mobility.

The disease is seen chiefly in ill-nourished persons of declining years, and is said to be more common in those of rheumatic ancestry or predisposition. But it may be observed in younger persons who have been subjected to depressing influences or to injury, and is occasionally met with in children. When it does occur in the young, the disease is extensive in its distribution and comparatively rapid in its progress. The writer has seen two very severe cases in female children before puberty.

The disease often seems to have its origin in injury, a sprain or blow upon a joint eliciting the first symptoms; yet the predisposing diathesis is doubtless also essential for its production, because the inflammation started by the injury leads to

results entirely different from those of ordinary traumatic arthritis, and, moreover, other joints besides the injured one subsequently become affected.

Osteo-arthritis is probably one of the few joint-diseases which commence in the articular cartilage. The earliest changes are observed in this tissue, which loses its proper smoothness and pearly grey colour, and becomes roughened, of dull yellow tint, wasted, and worn away at the points of greatest friction; while, at the same time, irregular and nodular thickening occurs at its edges, where least subjected to pressure. After a time the synovial membrane becomes vascular and thickened, and there is sometimes considerable effusion into the joint. Fluid distension of the joint is not, however, usually of long duration, nor is it a prominent symptom in this affection. As the disease progresses the cartilaginous outgrowths ossify, and similar formations occur about the margins of the joint-surfaces, especially at the insertion of tendons; at the same time, the wearing away of the cartilages exposes the bones, the ends of which become flattened out and the articular cavities enlarged, while their surfaces become hard, dense, and polished.

The neighbouring ligaments and tendons become softened, stretched, wasted, or completely destroyed; so that, in addition to the great alterations of shape which the bony outgrowths and flattening out of the joint-surfaces have produced, more or less displacement occurs. Moreover, some of these cartilaginous or bony formations may become detached into the cavity of the joint, and thus give rise to a so-called 'loose cartilage.'

The *symptoms* of course differ with the stage of the disease, and it is important to remember that the affection varies greatly in its rate of progress. At the commencement, aching pain and stiffness and crackling in the joint are the chief characteristics, to which, after a variable time, are added nodulation and displacement of the joint-surfaces, and alterations in the axes of the limbs.

It is the rapid occurrence of these later changes, especially after injuries, which gives rise, sometimes, to suspicions of fracture and to the erroneous diagnosis of partial dislocation. In the shoulder, the long tendon of the biceps may be completely divided, the glenoid cavity much enlarged, and the head of the humerus altered in shape, so that the natural outlines of the joint are not recognisable; and movement, which is too free in some directions and re-

stricted in others, is accompanied by loud crepitus. It is easy to see that these are conditions which, especially if they ensue upon an injury, may be misinterpreted by the sufferer, and possibly by his attendant.

So also in the wrist, the osteal changes may simulate displacement of the carpal bones; and in the hip-joint the flattening of the head of the femur, the shortening of its neck, the enlargement of the cavity and roughening of the margin of the acetabulum, and the destruction of the round ligament give rise to symptoms which may be mistaken for intra-capsular fracture.

It is well to bear in mind then, that in elderly persons, and in those predisposed to this disease, a fall on the hip, a fracture of the lower end of the radius, a sprain of the knee or a blow on the shoulder, are injuries which, amongst others, are frequently followed by the development of osteo-arthritis.

Treatment.—In the treatment of osteo-arthritis it is of the first importance to improve the nutrition of the patient, which will almost always be found defective. When, therefore, injuries such as those alluded to occur in elderly persons, or in those prematurely senile, or who are ill-nourished or suspected to have any predisposition to osteo-arthritis, a generous diet, in which oil and fatty food should have a large share, should be given during the treatment of the injury; while, at the same time, the nutrition of the injured limb should be promoted by warmth, friction, and other suitable measures.

In the early stages of the disease, warm douches, friction with oleaginous liniments, soft, warm supports to the joints, applied so as not to interfere with the circulation nor with moderate use of the limb, are the appropriate local treatment. Cod-liver oil, sulphur, arsenic, or guaiacum may be given internally. If, in spite of such measures, the disease is progressive, it is worth while for the patient to seek one of the sulphurous spas, where the treatment is often productive of great benefit.

In the advanced stages of the malady, attention to the general nutrition and the maintenance of warmth are the chief aids, but the local changes are of course irremediable. See CHRONIC RHEUMATIC ARTHRITIS; CHARCOT'S DISEASE.

J. WARRINGTON HAWARD.

OSTEIOD CANCER. See CARCINOMA.

OSTEOMA.—Osteomata are tumours composed wholly of bone, and attached by their bases or peduncles to some part of

the bony framework of the body. In some rare instances they have been found in the soft parts as distinct and discontinuous tumours, but these are exceptions with which there is not space here to deal. Under *Exostosis* will be found a description of osteomata which grow from or are attached to the different parts of the skeleton; and under *Jaws*, Diseases of the, the forms of osteoma of which these bones are the frequent seats have been described. Tumours composed of other tissues, in which ossification is present, will be found described under *ENCHONDROMA* and *SARCOMA*, those only in which ossification is complete being spoken of as osteomata.

H. H. CLUTTON.

OSTEOMALACIA.—Osteomalacia is a disease of the fully formed adult bones, in which bending or fracture of one or more of the osseous structures is liable to occur, with considerable deformity. Under *FRAGILITAS OSSII* will be found a description of the various forms of atrophy in which fracture is likely to take place, and which at times have been mistaken for osteomalacia.

Causes.—Very little has been ascertained as to the definite causation of this disease, but the circumstances predisposing to its occurrence (or, to speak more certainly, the circumstances under which it most frequently arises), are well known. Mr. Durham, in the *Guy's Hospital Reports*, 3rd series, vol. x., 1864, has carefully analysed Litzmann's cases, which number 131, and has added the particulars of 14 other cases, making a total of 145. The most striking feature in this analysis is the fact that out of a total of 145 there were 132 females and only 13 males, and 'of the females 91 were first affected during pregnancy, or very shortly after childbirth.' As regards the time of life, 'the great majority began to suffer when between twenty-five and thirty-five years of age.' The situation of the disease is also remarkable, for, in those cases connected with pregnancy, the pelvis and the lower part of the spine were the first to give any indication of the disease, and, in those unconnected with pregnancy, the symptoms very early manifested themselves in the lower extremities. After discussing the various circumstances in the life-histories of these patients to which the disease has been at times attributed, Mr. Durham thus expresses his own opinion:— 'In the histories of all, without exception, mention is made of the existence of some influence or other, or of some combination

of influences, well known to be capable of producing great general depression of the nervous system.' It would be out of place here to discuss the many theories that have been propounded to explain the reason why the bones should be so extensively diseased, whilst the rest of the tissues remain to all appearances unaltered. Nor is there space to enumerate the chemical theories which have been advanced, by different authors, to explain the absorption of the inorganic constituents of bone and the appearance of salts of lime in the urine. Suffice it to say, that lactic and phosphoric acids have each been considered to be the means of this alteration in the condition of the bones.

Pathology.—Osteomalacia consists essentially in a softening of the bone-tissue. The earthy matter is in the first place absorbed, leaving the organic matrix with only a faint indication of its lacunæ and canaliculi. The appearance is similar to that which is produced when bone is soaked in hydrochloric acid for a microscopical specimen. This change is first seen in the bone next the Haversian canals and medullary spaces, while the central portions of the trabeculæ have still almost the appearance of healthy bone. The decalcification proceeds more rapidly in one direction than another, and often produces semicircular excavations like Howship's lacunæ in rarefying osteitis. The central portions of the trabeculæ are gradually affected in a similar manner, while the parts already decalcified become soft and jelly-like. The Haversian canals thus gradually enlarge till the compact substance resembles spongy bone, and this again is transformed into a soft gelatinous tissue without any osseous trabeculæ at all. This process goes on till the whole of the interior of the bone is converted into a substance resembling jelly, leaving, however, a thin layer of the cortex beneath the periosteum unaffected. The fact that this outermost layer of the cortex, which is often not thicker than cardboard, remains unaffected, deriving, as it does, its nourishment from the periosteum, lends support to the theory that the disease starts in the medullary cavity. The vessels, no longer contained in rigid walls, allow their blood to escape, so that a reddish brown semi-fluid pulp is produced, resembling that of the spleen. This parenchymatous hæmorrhage is a very constant phenomenon in osteomalacia. Microscopically, this pulp is found to contain numberless blood corpuscles, cells of various shapes and sizes, but

mostly small, a considerable number of oil-globules, and granular matter.

The *symptoms* are at first somewhat obscure, the patient complaining only of pain, which is nearly always described as rheumatic. It is deep-seated and increased by pressure and motion; but there is nothing very definite in its character by which one can tell the onset of the disease. General lassitude and inability to make any exertion are commonly complained of, but it is not possible to say that osteomalacia is present till some very obvious deformity points out, only too clearly, the nature of the affection. Diminution of stature, and a peculiar gait in walking, may also at times be observed, the latter being apparently induced by a feeling of want of security. But all these symptoms could, at most, only arouse the suspicions of the medical attendant. The real state of the case is eventually revealed by the discovery of one or more bones becoming bent or broken from some very trivial accident. Or, possibly, the practitioner may first be made aware of the condition of the bones by an examination of the pelvis during parturition. The iliac and pubic bones are not infrequently the only parts at first affected. The promontory of the sacrum is thrust forward by the weight of the body, while the sides of the pelvis are made to approximate from the same cause acting upon the two femora. The pelvis thus assumes the beaked shape so characteristic of the deformity in this disease. It is needless to point out the serious obstacle which this condition of the pelvic outlet causes to the safe delivery of the child. Cæsarean section is, in many cases, the only resource of the obstetrician. The bones, being soft, however, have been bent and altered in shape by the hands of the medical attendant, and delivery effected through the vagina.

The spine also is oftentimes very seriously deformed, and chiefly by the great increase of its natural curvatures, which may be so much exaggerated as to assume somewhat the shape of the letter S. The ribs also may bend or break from the action of the respiratory muscles and the use of the upper extremities. They commonly yield and bend outward not far from the spine, and are again thrust forwards just outside the sternum; and between these two points, at the axillary line, they are bent inwards. The arms are thus lodged in trough-shaped hollows, and tend to compress the lungs within the chest. The bones of the extremities have also been

bent and broken in many places, allowing the feet to touch the head in some extraordinary instances. We may thus have, in extreme cases, the most exaggerated deformities of the skeleton of which the human body is capable. But it is quite possible for the disease to be confined to the pelvis and the lower part of the spine, as has been shown in the statistics quoted above. The urine has almost always contained an excess of lime-salts, pointing to the conclusion that the inorganic constituents of bone are eliminated through the kidneys. Fever has also been noticed towards the termination of many of the cases, but in the early stages it has generally been absent.

It is impossible to give a very definite or decided opinion as to the mortality of osteomalacia. A very large proportion of the deaths have occurred during parturition from the mechanical difficulty to which the deformed pelvis has given rise. But it does not appear that the disease itself directly causes death. The patients are necessarily confined to bed, and as a consequence their vital powers are considerably diminished. They are thus exposed to intercurrent maladies, which may at any time prove fatal in such enfeebled constitutions as are necessarily produced from the conditions of the disease. Provided the thorax and spine are not involved, the patients may live a very long time in their crippled and bedridden condition. But if the ribs give way and cause compression of the lungs, or the softening of the bodies of the vertebræ interferes with the integrity of the spinal cord, a fatal termination may quickly supervene and cut short a long and tedious complaint. If none of these casualties occur, the patient may eventually die of exhaustion and simple failure of the vital powers, in a manner similar to that seen in extreme old age.

Recovery or obvious improvement is stated to have occurred in 22 out of the 145 cases already quoted from Mr. Durham's article. But they appear to have been nearly all connected with pregnancy, and the disease was confined to the pelvis and the lower part of the spine. How far such cases of osteomalacia are really capable of recovery, further experience is required to show.

Treatment.—There is very little to be done in the way of treatment. In the early stages, freedom from anxiety, absolute rest, good diet, and general tonics such as iron, quinine, and cod-liver oil, should be recommended. Salts of lime would seem only to be capable of doing harm, for the system

is trying, through some error of nutrition, to get rid of what is already present in the tissues, as is evidenced by the condition of the urine; and to throw more upon the organs already overburdened with these salts, only tends to increase their difficulties. Should a definite fracture occur, it must be treated on ordinary principles, in the expectation that it will unite, as it generally does in the early stages of the malady. In extreme cases, there is really nothing that can be recommended to arrest the progress of the disease.

H. H. CLUTTON.

OSTEOMYELITIS is an inflammation of the medullary canal and the tissue lining the cancellous parts of bone. It may be divided into acute and chronic osteomyelitis. Of the acute there are two very distinct varieties.

SIMPLE ACUTE OSTEOMYELITIS is generally caused by some definite injury to the bone, as in fractures or gunshot wounds. The inflammatory exudation takes place as it does in other tissues, and may undergo the same changes of resolution, suppuration, or organization. It occupies the tissue lining the cancellous framework of bone and, in simple fractures, forming the internal callus which will be found described in the pathology of this form of injury. In compound fractures, and after amputation, it often terminates in suppuration or necrosis of a limited portion of the cancellous tissue. This simple form of inflammation, confined as it is to a small portion only of the medullary canal, gives rise to no symptoms to distinguish it from the particular injury of which it plays only a secondary and unimportant part. The treatment may be gathered from what is said, in the following sections, as to the best means of preventing the diffuse form of the disease.

ACUTE DIFFUSE OSTEOMYELITIS is a much more serious complaint, corresponding to the acute diffuse periostitis which it sometimes accompanies. They are both thought by many surgeons to be infective or due to some specific virus. This is the form of inflammation which is generally meant when the term osteomyelitis is used, the simple inflammation being usually omitted from consideration, as having only a pathological interest.

Causes.—An *idiopathic* form of this disease, which is described as occurring in other countries, is very rare in England, except in so far as it may accompany and be a part of acute diffuse periostitis. The *traumatic* variety is, however, well known

in civil practice in England, and is especially dreaded by military surgeons in time of war.

Amputations, compound fractures, and gunshot injuries involving bone are the cases in which it is prone to occur. Decomposition of the discharges of a wound communicating with the medullary canal is undoubtedly, in most cases, the essential cause. It is, consequently, much less common in the present day, when so much is done, and that successfully, to prevent putrefaction and decomposition of wounds. Erysipelas and hospital gangrene and like infective inflammations may attack the medullary canal, but are scarcely likely to do so unless the discharges are in a septic condition. The state of things which then arises does not differ clinically from the disease we are now considering.

Pathology.—The simple mechanical process, by which this form of osteomyelitis takes place in a decomposing, suppurating wound, is easy to understand, without looking for a specific virus as an explanation. The patulous, thin-walled veins, lying embedded in such a rigid inelastic material as bone, at the bottom of a deep and suppurating wound, may very easily become distended with pent-up inflammatory exudation, which, for want of a ready outlet, may decompose and give rise to that septic mischief which we know and recognise as one of the chief constitutional signs of osteomyelitis. From the part thus affected the inflammation may spread to the adjoining medullary tissue, and the products of this inflammation, finding no outlet, may so arrest the circulation as to cause necrosis, or decompose and still further spread the mischief. Finally, the whole of the medullary canal, from one end to the other, may be affected in this way. Putrefaction of a wound may thus be alone responsible for a diffuse osteomyelitis, without the intervention of a specific virus. The veins filled with decomposing septic material may very easily give rise to embolic pyæmia, for they cannot collapse, and thus quickly become thrombosed. The thrombus softens from decomposition, and particles becoming detached enter the circulation, to be arrested in a distant part of the body. The patient may, however, especially after an amputation, where there is a more open surface for the escape of the inflammatory and decomposing products, live through these dangers. More or less extensive necrosis is then almost certain to follow, involving the cancellous tissue and the inner layer of the compact bone. The

long ferrule of bone, withdrawn in the form of a sequestrum from a stump some months after an amputation, is the common and most favourable result of this diffuse osteomyelitis.

Symptoms.—Deep-seated swelling of the soft parts covering the bone affected, whilst the skin remains almost in its natural condition; severe, dull, aching pain and much tenderness on pressure, are the chief local symptoms. Profuse discharge of dirty-looking, offensive pus from the wound or stump, increasing in quantity as time goes on instead of becoming less, as it should do under healthy conditions, would add to the probability of the medullary canal becoming inflamed and the source of all the trouble. Where the bone is exposed and capable of being examined, the periosteum will be found swollen, vascular, and detached from its connections. It may also be seen, as in the case of the skull, to be dry, yellow, and dead. If the medullary canal can be examined with a probe, as in the case of a stump, it will be found soft and yielding. But, oftentimes, there will be nothing by which to distinguish such a case from simple septicæmia or pyæmia. In fact, little can be said in most cases from the local symptoms; and we judge rather from the signs of septic mischief that there must be some source of infection. If the appearance of the stump be not inconsistent with some deep-seated mischief in the bone, we think it not improbable that the medullary tissue, although invisible, is the source of such severe constitutional symptoms. Fever of a septic type, with profuse sweats and much depression, are the principal features of this condition to which we are alluding. The temperature will probably be very high, between 103° and 105° Fahrenheit. Rigors may also occur and be frequently repeated. All the symptoms of pyæmia and septicæmia may become established, and the patient sink from rapid poisoning, or linger on with multiple pyæmic abscesses.

Treatment.—In the case of wounds and operations involving bone, let the disease itself be avoided by thorough cleanliness, and by that most perfect form of cleanliness—Listerism. If this be carried out in principle, although possibly not in absolute detail, decomposition will be prevented, and an almost absolute guarantee will be obtained that the mischief has not entered through the wound.

Other superficial and insignificant wounds may, however, be the channel through which septic poisons enter the cir-

culatation, and then decomposition may ensue in spite of all antiseptic precautions. We are not now speaking of those cases in which acute diffuse periostitis (or acute necrosis), with accompanying osteomyelitis, takes place without any wound whatever.

Granted then that putrefaction has occurred and the symptoms of osteomyelitis have ensued, what treatment is to be adopted to arrest its progress and prevent the onset of pyæmia? The two diseases are so liable to glide insensibly into one another, that whatever is done must be done quickly. First and foremost, a free outlet must be given to any pent-up discharges. In the case of a stump, the openings should, if small, be enlarged, and a drainage-tube be introduced. In the case of a compound fracture, an effective counter-opening may be required, so that the pus may escape as fast as it is formed. Then the question arises whether more than this can be done.

Amputation has been resorted to, with good results; but it must be done early, before pyæmia has become fully established, or the operation will be of no practical use. Some surgeons have asserted that, if amputation is performed, it is useless to do less than remove the whole bone—that is, to do exarticulation at the hip if the case be one of osteomyelitis of the femur. The writer of this article has, however, seen good results after removal of a portion of the bone, where the whole was not diseased. If amputation has been resolved upon, the decision as to the amount to be removed should rather rest upon the condition found upon examination of the end of the bone. If, after its exposure and examination with the finger, the periosteum is found extensively retracted, and the probe introduced into the medulla encounters nothing but pus and dead bone, the whole of the shaft should, if possible, be removed. When the probe comes rapidly upon sound and bleeding medulla, a portion only of the shaft need be taken away. Should, however, the sawn surface be still unhealthy, another section must be removed. In the case of the femur of an exhausted patient, it might be desirable, in the more extensive variety above-mentioned, to saw through the bone just outside the joint or through the trochanters.

Another and less severe operation has of late been suggested, and certainly deserves a trial in any case in which, for some reason, amputation is unsuitable. It consists in scraping out the whole of the diseased medulla and introducing iodoform into the canal. As far as general treatment

is concerned, the same rules apply here as in other exhausting febrile diseases. The patient must be supported with a stimulating, nutritious diet, and every method tried to keep his flagging powers from failing.

CHRONIC OSTEOMYELITIS.—Chronic inflammation of the medullary tissue takes place most frequently in conjunction with chronic osteitis and periostitis. *See* OSTITIS. It produces, however, no symptoms in these cases, except such as are common to the general inflammation of the whole thickness of the bone. The results of this condition are well seen in the filling up of the medullary canal in osteosclerosis. It sometimes takes another form, and terminates in suppuration or necrosis of a small portion of the cancellous tissue, producing the disease known as chronic ABSCESS OF BONE. H. H. CLUTTON.

OSTEO-PLASTIC RESECTION. *See* JOINTS, Excision of.

OSTEOPOROSIS.—Strictly speaking, osteoporosis is a spongy, porous condition of bone resulting from rarefying osteitis. The specimens in our museums are mostly enormously thickened skulls, in which the increase in size is almost entirely due to a development of finely porous and reticulated bone. In fact, their appearance is exactly similar to the condition described under OSTITIS DEFORMANS, and conveys the impression that if the history were complete, or if the whole skeleton could be examined, these thickened skulls, which were labelled many years ago as osteoporosis, would now be described as cases of osteitis deformans.

Besides the general effect produced by this disease, which is described elsewhere, a bone may become osteoporotic from local causes. An aneurism, or a tumour which only secondarily presses upon, but has not started in, the substance of a bone, may induce a local osteoporosis. But the term is more generally applied to the condition alluded to above, which arises without known cause, and affects many bones at the same time and in the same manner. H. H. CLUTTON.

OSTEO-SARCOMA. *See* SARCOMA.

OSTEOTOMY. — *Definition.* — Osteotomy, in its broadest acceptation, may be defined as the process of making a section of bone. It is, however, generally employed in a much more restricted sense, the term being applied to such divisions of bone as have been proposed and undertaken for the

relief of deformity, for the rectification of badly united fractures, and for the straightening of limbs which are fixed in bad positions by ankylosis.

Instruments.—When a surgeon is about to perform an osteotomy, his attention is directed towards the kind of instruments required, and the success of the operation depends in great measure on their proper selection. A variety of instruments has been employed, but the choice practically lies between the saw and instruments of the chisel order. Some surgeons prefer the saw to the chisel, as they believe that it is much more easily used, and they state that it is equally efficient. Langenbeck believed that the bone-*débris* left by the saw in the wound was apt to excite irritation which led to suppuration; and though this result does not necessarily follow, still, as it is an element of risk, it is better to avoid it. In the selection of an instrument, the desideratum is to secure one which will effect the osseous division with the least disturbance of the soft parts. When the saw is introduced by a subcutaneous wound for the performance of an osteotomy, there is the danger of laceration of the soft parts on either side of the bone while the saw is in action, besides the likelihood of air being pumped into the tissues by the to-and-fro movement. The chisel is not liable to these objections. Once the cutting edge is passed through the soft tissues to the bone, there is nothing further to fear; it in no way lacerates the soft parts, and it makes a fine, clean, osseous incision without leaving *débris*. It is, however, a most powerful instrument, and its proper selection and method of use are highly important to a successful issue of the case.

The instruments used by the writer are of two kinds, the chisel and the osteotome, the former being of the same form as the carpenter's, though different in temper; the latter being shaped like an attenuated double inclined plane. The chisel is used for paring, shaving, and cutting out wedges of bone, such as removing a cuneiform portion from the tibia in anterior curvature. The osteotome is used only for making simple incisions, or wedge-shaped openings, without removal of bone. It is advisable that anyone wishing to use these instruments should practise on the subject or on the bones of animals, so as to familiarise the hand and acquire the necessary dexterity. The surgeon should himself see that the instruments are scrupulously clean, before he uses them on the living body. If they are used while dirty, they will pro-

bably clean themselves in the wound, leaving in the soft parts or on the bone the foreign substance, and so possibly inoculate the tissues with decomposing matter. The only other instruments required are an ordinary sharp-pointed scalpel, suitable for penetrating the tissues to the bone, a couple of blunt hooks, and a mallet of hard wood, such as *lignum vitæ*.

The Operation.—The patient ought to be placed fully under the influence of an anæsthetic, and this should be maintained during the performance of the operation, and until the limb is securely fixed in splints. After the patient is fully anæsthetised, the limb is rendered bloodless. This is best done by the application of a bandage of elastic webbing, applied from the distal extremity of the limb to above the seat of operation, and then fixed at the most convenient point on the proximal aspect. The limb is then placed on a sand pillow. The sand pillow used by the author is eighteen inches by twelve; the case being filled with sand just sufficiently to enable it to be shifted from one part of the bag to another, without leaving any portion empty—a moderate fulness without distension. The sand is moistened just before the operation, to prevent the escape of dust and to produce greater cohesion between its particles, so that it will more readily retain the form or mould imparted to it. It is then covered with a sheet of jaconet or other waterproof material, and laid on a table. The limb is then embedded in the pillow in the manner suitable for the particular operation.

In order to introduce either the saw or the osteotome, a wound in the soft parts must be made. This wound ought to be a sharp, clean, single incision, produced by one stroke of the instrument wherever this is practicable. Dissection ought to be avoided, the situation in which the incision is to be made being chosen so as to get to the bone as directly as possible. The direction of the incision should be in a line with that of the muscular fibres about to be penetrated. The situation of the wound in the soft parts ought to be selected so as to avoid cutting, not only the larger vessels, but also the smaller ones, when this can be done. As to the extent of the incision, this depends greatly on the surgeon, whether he wishes to see what he is doing, or whether he can trust to the tactile sensations conveyed through the instrument to his hand, as a sufficient guide. If the latter, the wound need only be large enough to admit the osteotome; if the former, it would require to be a couple or more inches in

length, according to the depth of the tissues. When a surgeon commences to practise osteotomy, it would be well for him to make a large incision, one sufficient to enable him to examine the bone with the finger, or even to see the bone; in this way he performs his operation with more confidence, and the extent of his incision is an element of safety, inasmuch as it provides a ready exit for discharge—blood or serum—which otherwise might be pent-up in the parts, causing distension. After he has gained a little more experience, the osteotome may be used as a probe (the saw will never answer this purpose), the sensations conveyed through the instrument being sufficient to enable the operator to ascertain all that can be known by the introduction of the finger. When the operator has reached this stage, all that is necessary is to make an incision which will enable the osteotome to reach the bone—from half an inch to an inch long, according to the breadth of the blade. By operating in this way the tissues are much less disturbed, there is less effusion of blood or serum, and much less need of drainage.

In removing wedges of bone, the wound must be larger. But, in operating upon the tibia, the incision need not be larger than the base of the wedge to be removed, as the skin moves freely over the surface of the bone, and may be shifted up or down to suit the convenience of the operator. When small wounds are made, the knife ought to remain *in situ* until the saw or the osteotome is introduced by the side of it to the bone, the knife acting as a guide. When the osteotome has reached the bone, it should be turned in the direction in which the osseous incision is to be made, care being taken while doing this not to denude the bone of periosteum.

The osteotome ought to be used in such a way as to direct its cutting edge away from any important soft structures, which it may be necessary to avoid. As the osteotome has blunt sides, it may be used to lever the soft tissues aside, keeping, meanwhile, the cutting edge of the instrument in close contact with the bone. After a little practice, the osteotome acts as a probe, and when once the tactile impressions conveyed through this instrument are cultivated, it becomes a delicate indicator of the state of the bone, the precise relation of the osteotome to it, and the extent of the osseous incision. But when the osteotome has been embedded in the bone for an inch or two, its delicacy of touch is lost, and it no longer remains a precise indicator of what is in

contact with its cutting edge. This is due to the manner in which the sides of the instrument are pressed on and caught by the bone; the amount of lateral pressure varying according to the amount of the osseous tissue through which the instrument passes. This may be easily rectified by introducing a finer instrument by the side of the thicker one first used, and withdrawing the latter. The finer instrument is then placed in the osseous groove made by the thick one, but, being a more attenuated wedge, its sides are not pressed on, so that it acts as an indicator of the kind of tissue in immediate contact with its cutting edge. This can be repeated, in a thick bone, by the substitution of a third instrument of still greater acuteness.

When using the osteotome, it ought to be grasped firmly in the left hand, steadied by the inner border resting on the patient's limb. The surgeon ought to cut to, instead of from, himself. Thus, if the surgeon is operating on the inner side of the left limb, he ought to stand on the left side of the patient, and cut towards himself. If the surgeon, instead of following this instruction, should hold the osteotome loosely, a slightly uneven blow with the mallet would outweigh his grip, and might cause the instrument to slide along the surface of the bone, peeling the periosteum, or causing a more unpleasant accident, such as penetration of an artery. When the chisel is placed in position, the mallet may then be brought into requisition, being used by the right hand. When the external shell of bone is felt to have given way, it is not advisable to attempt to complete at once this particular portion of the section, because the instrument is apt to be caught. In order to avoid impaction, the entire superficial portion of the section ought to be completed in the first instance, so as to permit a little movement of the instrument in the direction of its breadth; and by making a series of such movements, after each impulse given by the mallet, there can be no fixity. The osteotome or chisel ought not to be pressed against the bone transversely to its breadth, as it is possible that it may be broken or twisted by so doing. The bone itself may be splintered longitudinally by such pressure. In no instance should the osteotome or chisel have a breadth greater than the diameter of the bone about to be cut, otherwise the soft structures at either side are apt to be injured. When a large wedge is to be removed, it is better to do this in several pieces—first a small superficial

wedge, then a shaving of each side until the desired extent is reached. The form of normal bone, as it appears in section, may be of some use in guiding the direction of osseous incisions; but this cannot be absolutely depended on in the case of distorted bones, as their contour is often greatly altered. It may be borne in mind that rachitic bones have a tendency to become flattened, sometimes in one direction, sometimes in another, and that when the bone is curved, the concave portion has the thicker wall as a rule.

OSTEOTOMY FOR THE RELIEF OF ANKYLOSED HIP-JOINT, WHEN AT AN ANGLE PRODUCING DEFORMITY.—In such cases, the neck of the femur is divided so as to enable that bone to be brought down into a straight line with the body. Adams performs his operation with a saw, and thus describes it: 'The left thumb is placed firmly, so as to compress the soft tissues solidly against the bone, at a point situated at the centre of the top of the great trochanter, and the breadth of one finger above. At this point the narrow-bladed knife is pushed in till it reaches the neck of the femur, at a right angle across the front of which it is then carried. The knife is then gently moved to cut a space for the easy insertion of the saw, which, traversing the course of the knife, reaches the front of the neck of the femur and gradually cuts it completely through. The surgeon cuts until he feels that the saw is free of the bone, and moving in the soft tissues only, behind the bone.' The neck of the femur may also be divided by the osteotome, that instrument being introduced at the same place as is indicated above, and with a few blows of the mallet the division is completed. In certain cases, where this operation of division of the neck of the femur cannot be performed on account of the femur being firmly held by cicatricial tissue, or where the muscles and tendons surrounding the joint are much contracted, or where the neck of the femur is altered by absorption or by deposition of bone, Mr. Gant divides the femur immediately below the lesser trochanter. By doing so the limb is restored to the straight position, but is apt to be made somewhat shorter.

OSTEOTOMY FOR ANKYLOSIS OF THE KNEE-JOINT.—When angular ankylosis of the knee-joint is present to such an extent as to render the limb useless for walking, or only permits the toes to reach the floor, the limb may be rendered straight by osteotomy. This operation must not be performed so long as there is any active disease

present in the joint. In this case, the femur may be divided at the same level as for genu valgum; only, the anterior portion of the bone ought to be divided completely over its whole breadth, so as to permit of straightening from behind forwards. If the deformity has assumed nearly that of a right angle, it is possible that this linear osteotomy may not be sufficient to rectify the whole deformity. Under such circumstances, instead of removing a wedge from the femur, it is better to make another linear osteotomy just below the tuberosity of the tibia, or a little to the proximal side of this. When the deformity is great, it is better to have recourse to gradual straightening after the operation, as the sudden strain of complete straightening, on the vessels of the popliteal space, might lead to bad results. The limb may be safely straightened so long as the tibial vessels at the ankle pulsate freely. The straightening ought to be completed during the first week, if possible.

OSTEOTOMIES FOR GENU VALGUM.—Ogston's operation is as follows:—The knee is flexed as fully as possible. A long tenotomy knife is introduced flatly two or three inches above the inner condyle, and pushed downwards, forwards, and outwards, until the point is felt in the intercondyloid space. The cutting edge of the tenotome is then turned downwards, and the soft tissues are divided to the bone as its withdrawal is effected. Adams's saw is then introduced along the groove formed by the knife, and the inner condyle is sawn through, from above downwards, for about three-quarters of its thickness. The fracture is completed by forcibly straightening the limb, the loose condyle slipping upward over the sawn surface. This operation may also be performed by the chisel instead of the saw. Professor Ogston has recently expressed a preference for the operation about to be described.

MACEWEN'S OPERATION FOR GENU VALGUM.—The limb being rendered bloodless, is placed on a sand pillow, where it is securely held by two assistants. One assistant, standing on the opposite side of the table from that of the operator, places his right hand on the thigh, while the other, standing at the foot of the table, places his right hand on the upper part of the tibia. The operator sponges the seat of operation with 1-20 carbolic watery solution; the spray is then directed on the part. A sharp-pointed scalpel is introduced on the inside of the thigh, at a point where the two following lines meet—one drawn

transversely, a finger-breadth above the superior tip of the external condyle, and a longitudinal one drawn half an inch in front of the adductor magnus tendon. The scalpel here penetrates at once to the bone, and a longitudinal incision is made sufficient to admit the largest osteotome and the finger, should the surgeon deem it necessary. Before withdrawing the scalpel, the largest osteotome is slipped by its side until it reaches the bone. The scalpel is withdrawn, and the osteotome, which was introduced longitudinally, is now turned transversely in the direction required for the osseous incision. In turning the osteotome, too much pressure must not be exerted, lest the periosteum be scraped off. It is then convenient to pass the edge of the osteotome over the bone until it reaches the posterior internal border, when the entire cutting edge of the osteotome is applied, and the instrument is made to penetrate from behind forwards, and towards the outer side. After completing the incision in that direction, the osteotome is made to traverse the inner side of the bone, cutting it as it proceeds, until it has divided the uppermost part of the internal border, when it is directed from before backward towards the outer posterior angle of the femur.

In cutting on these lines there is no fear of injuring the femoral artery. The bone may be divided without paying heed to this order of procedure, but it is better that the operator should have a definite plan in his mind, so that he may be certain as to what has been divided and what remains to be done. The writer is persuaded that accidents have happened by not paying heed to this. In using the osteotome, the left hand in which it is grasped ought to give, after each impulse supplied by the mallet, a slight movement to the blade—not transversely to its axis, but longitudinally—so as to prevent any disposition to fixity which it might assume. After the inner portion of the bone is divided, a finer instrument may be slipped over the first, which is then withdrawn; and even a third, if necessary, may take the place of the second when the outer portion of the bone comes to be divided. Whether one or more osteotomes be used depends much on the resistance met with. If the tissue is yielding, one may suffice; if hard or brittle, two or three will effect the division more easily, and with less risk of breaking or splitting the bone longitudinally. In the adult, the dense circumferential layer of bone resists the entrance of the osteotome at the outset, but several strokes cause the instrument

to penetrate this superficial dense portion, when it will pass easily through the cancellated tissue. After a little experience, the surgeon recognises, by touch and sound, when the osteotome meets the hard layer on the outer aspect of the bone. If it be considered desirable to notch or penetrate this outer dense part of the bone, in doing so the osteotome ought to be grasped firmly by the left hand, the inner border of the hand resting on the limb, so as to check instantly any impetus which may be considered too great. It is better to snap or bend this layer rather than cut it. When the instrument is to be altered in position, it ought not to be pulled out in the ordinary way, as it is then liable to be removed from the wound in the soft parts, as well as from the bone. Instead, let the left hand, with its inner border resting on the limb, grasp the instrument, while the thumb is pressed under the ridge afforded by the rounded head, and gently lever the osteotome outwards by an extension movement of the thumb. In this way the movement may be regulated with precision. It is desirable to complete all the work intended by the osteotome before removing it from the wound.

When the operator thinks that the bone has been sufficiently divided, the osteotome is laid aside and a sponge, saturated in 1-40 carbolised watery solution is placed over the wound. While the surgeon holds the sponge he, at the same time, employs that hand as a fulcrum; with the other he grasps the limb lower down, using it as a lever, and jerks, if the bone be hard, or bends slowly, if the bone be soft, in an inward direction, when the bone will snap or bend as the case may be. The limb is then brought into a straight line. A sponge, saturated in 1-40 watery solution, is placed over the wound, and kept in position by a gauze bandage. This is retained until the opposite limb is operated on. After the wound is thus protected, the elastic webbing controlling the circulation is removed, and the limb is held by an assistant, who practises extension meanwhile. After the other limb has been operated on, it is similarly treated while the first is being dressed. Before applying the dressing, any redundant cellular tissue, which may protrude from the wound, ought to be removed by a pair of scissors curved on the flat. The wound is then dressed antiseptically and placed in a special splint. The splint is a modification of the half box, the outer portion being carried up, like a long splint, to about the level of the third or fourth rib, and projecting beyond the posterior splint

at the foot. This projection is fixed in the clamp of a bed-rest, and so the whole limb and splint are kept motionless and steady.

Although osteotomy may be performed without antiseptics, there is an element of risk in so doing. The writer uses strict Listerian precautions in his operations, with the addition of a little iodoform on the inner dressing, when it has to remain on the wound a fortnight or longer. He is further of opinion that, when suppuration ensues after an antiseptic osteotomy, it is almost always due to irritation produced by violence (which is never needed and ought to be avoided), either to the bone or to the soft parts, especially the latter. In cuneiform osteotomies on the tibia, where the wound, both in the soft parts and in the bone, is larger than in linear osteotomies, and consequently more exposed to contamination, the writer has never had suppuration.

WILLIAM MACEWEN.

OSTEOTRITE.—A mill-headed instrument invented by Mr. John Marshall, for smoothing the walls of bony cavities, and for enlarging bony sinuses.

OSTITIS.—Ostitis, or inflammation of bone, is often meant when the word periostitis is used. Inflammation rarely attacks either the periosteum, the compact tissue, or the medulla alone, but clinically the distinction is of value, inasmuch as it indicates the part which is primarily or principally involved. Neither the periosteum nor the medulla is free from inflammation in ostitis, but by the word ostitis the compact tissue of bone is indicated as the primary seat of disease. It most commonly affects the shaft of a long bone, and by preference the tibia or femur.

Causes.—Injuries of various kinds are probably the most common exciting causes of ostitis. Fractures, simple and compound, gunshot wounds, amputations, contusions, burns, and extreme degrees of heat or cold may give rise to it. Injuries of a less serious kind may also be the exciting cause of ostitis, in a subject already inclined to such inflammation. The predisposing causes are syphilis, both hereditary and acquired, struma, and tubercle; both of the latter, however, generally terminate in caries. It also occasionally follows rheumatism and typhoid fever.

Pathology.—In simple ostitis the bone, periosteum, and medulla become more vascular. The Haversian canals enlarge, whilst inflammatory exudation takes place in the connective-tissue around its vessels. The

periosteum is swollen and infiltrated with serum and leucocytes, and is easily separable from the bone, whilst the medullary tissue is similarly engorged. The osseous lamellæ are eroded from absorption, forming Howship's lacunæ, and the notches thus made are filled with embryonic connective tissue. A large number of multi-nucleated cells, called 'osteoclasts,' are found in this tissue, which are supposed to play a not unimportant part in the absorption of bone. In this condition the process is called *rarefying ostitis*, but, coincidentally with this rarefaction, new bone is being formed in the outlying parts beneath the periosteum and in the central canal. The small nucleated cells that take part in this new formation are called 'osteoblasts.' In simple ostitis the two processes are at first constantly going on together. Then, the subsequent changes will vary according to the intensity of the inflammation. Under favourable circumstances the inflammatory new-formation may undergo resolution, and the bone return almost to its natural condition; as a general rule, however, the bone remains somewhat larger from the amount of new material which has been formed around the inflamed area, and becomes, possibly, somewhat denser.

Condensing Ostitis or Osteosclerosis.—As a further development of the same process the ostitis may terminate in osteosclerosis. The inflammatory exudation in the connective tissue surrounding the vessels in the Haversian canals may organise into new bone, and thus fill up the spaces that had been previously formed, and even still further encroach upon these narrow channels till the bone becomes denser and harder than in the normal condition. This condensation may develop to such an extent as to convert the bone into a tissue as hard as ivory. The vessels may even be completely obliterated, as a consequence of the obstruction to the circulation, and the death of a considerable area of bone may in this way take place. The periosteum at the same time develops new bone as is shown under PERIOSTITIS, so that the original bone is increased in size as well as in density. The medullary canal is also encroached upon, and its cavity almost obliterated. This condensing ostitis or osteosclerosis is essentially a very chronic process, and may occur, especially in syphilis, without the preceding stage of rarefying ostitis.

Abscess.—Rarefying ostitis may, also terminate in suppuration, the inflammatory exudation, as in other tissues, forming

granulations and breaking down into pus. This is the ordinary termination of ostitis around a piece of dead bone and in compound fracture. It also not infrequently occurs in simple ostitis of the cancellous tissue, producing the well-known chronic ABSCESS OF BONE which is more fully described under that title. The inflammatory products may also, under certain circumstances, be so quickly formed as to compress the vessels in the Haversian canals and cut off the circulation from a part of the bone, thereby causing its death. The subsequent changes are described under NECROSIS.

Symptoms.—Inflammation of the compact tissue of bone is a chronic affection, beginning slowly and insidiously with obscure dull aching pains, which are worse at night and in wet weather. It may make considerable progress without giving any appreciable sign, except the persistent pain at night, which generally comes on in the evening whilst the patient is sitting over the fire, or getting warm in bed, and keeps him awake for many hours. On examination of the part complained of, it is often found that the bone is already somewhat larger than its fellow, and tender on pressure. As the disease almost always has its seat in the shaft of one of the long bones, especially the femur and tibia, these obscure, persistent, aching pains in any of the limbs should lead to a careful examination of the bone in its whole length. The enlargement will not be absolutely uniform, so that the irregularity can be easily detected by grasping the bone between the finger and thumb, and feeling it in this way from one end to the other. In syphilis, the corresponding bone on the opposite side of the body will be very often found in a similar condition. Tenderness on pressure will vary considerably, according to the sensitiveness of the patient and the stage of the disease. At first it is often well marked, whilst later on it is much less perceptible. There is not often much, if any, swelling of the soft parts, except in the case of wounds and compound fractures. But occasionally, and this chiefly in the tibia, where the bone is superficial, there may be some slight cedema and 'pitting' on careful pressure. Of course in the case of abscess of bone, which, however, does not generally affect the shaft, the condition is different, and will be found described under chronic ABSCESS OF BONE.

Treatment.—Iodide of potassium, in gradually increasing doses, should always be tried. Five, ten, or even fifteen grains may be given three times a day, if the

smaller doses produce no diminution in the severity of the pain. Generally, however, the patient is greatly relieved in quite the early stage by the smaller doses, and this effect is produced in most cases whether the patient be the subject of syphilis or not. In some few instances that have come under the writer's notice, where syphilis was undoubtedly present, the addition of mercury in the form of pil. hydrargyri, gr. v. nightly, has produced a more lasting and permanent improvement, after iodide of potassium alone had failed to accomplish more than a temporary diminution of pain. The application of blisters will also sometimes give relief. Painting with the strongest iodine liniment, or rubbing the affected part with mercurial ointment may be tried, and will occasionally prove serviceable, but iodide of potassium is, as a rule, the most potent remedy where the disease has not become fully established. Unfortunately, in the chronic cases, where the bone has become thickened and enlarged in spite of the treatment employed, nothing can be done to effect a completely successful result. If there be little or no pain, the patient has some inconvenience from the size of the bone and its weight, but he generally learns, in the course of time, to put up with this discomfort. On the other hand, should the pain continue to be a source of serious annoyance, linear osteotomy or the application of the trephine to the most tender spot, will often give the most marked relief. A simple incision through the periosteum is sometimes sufficient, especially in the early stage of the disease, where other less severe measures have failed to effect any improvement. In the later stages, linear osteotomy is probably the best operation, as it gives relief to a larger area of bone than the simple removal of a circular piece by the trephine. The bone should be thoroughly exposed by the knife to the extent of three or four inches, and a groove be cut in it with a chisel or a Hey's saw, till the medullary canal is reached. The bleeding that necessarily ensues relieves the engorged bone, mitigates for a very long time, if it does not entirely remove, the pain, and lessens the chances of subsequent suppuration or necrosis.

H. H. CLUTTON.

OSTITIS DEFORMANS.—Sir James Paget's description of this disease, in the *Medico-Chirurgical Trans.*, vol. ix., 1877, is the first in which the symptoms and history are collected together in a definite form, under the name of ostitis defor-

mans. To him, indeed, we owe the fact that, since the publication of the above paper, one more obscure bone-disease has been reclaimed from the unclassified group of osseous deformities, which still remains in our museums with an incomplete life-history.

Cause.—Nothing whatever is known as to its etiology. Neither syphilis, rheumatism, gout, scrofula, nor tubercle can be said to have a direct influence in this respect, for there is no clear history of these affections running through any considerable proportion of the recorded cases. In three out of the first five cases reported by Sir James Paget, cancer made its appearance late in life. But in seven others, recorded by the same author in vol. lxxv. of the *Medico-Chir. Trans.*, 1882, cancer was not found to be associated with any one of the cases.

Pathology.—It would seem to be a form of chronic inflammation, beginning in old age or after middle life, and affecting principally the long bones and those of the skull. In Sir James Paget's words: 'The bones enlarge and soften, and those bearing weight yield and become unnaturally curved and misshapen.' While increase in size and alteration in shape are the principal external features of the disease, the texture of the bone is not less altered. The normal osseous tissue is replaced by a finely porous substance which, though reticulated and porous, is yet denser than it naturally should be. The strength of this bone is evident, and one can scarcely conceive it possible that bone in this condition could bend, especially when its enormous increase in size is taken into consideration. Such specimens only come under our observation quite late in the course of the disease. It is, therefore, probable that, at an earlier date, the bones atrophy and soften, and then become bent from the weight of the body; and that, subsequently, they undergo those hypertrophic changes which we see so largely developed in the advanced condition of the disease, at which they usually arrive before simple old age or some intercurrent malady terminates the patient's existence.

A splendid specimen of a whole skeleton, obtained by Mr. J. R. Lunn, is described and graphically depicted in *St. Thomas's Hospital Reports*, vol. xiii., 1883. The microscopical appearances, described by Dr. Sharkey, show that the principal feature in the change is one of rarefying ostitis. The complete skeleton, now in the museum of St. Thomas's

Hospital, is quite a unique specimen, and its coarse anatomy is most beautifully shown in the engravings illustrating the paper in the Reports above mentioned.

The *symptoms* are first noticed, as stated above, after middle life or in old age. 'The most characteristic,' according to Sir James Paget, 'are the loss of height, indicated by the low position of the hands when the arms are hanging down; the low stooping, with very round shoulders and the head far forwards with the chin raised, as if to clear the upper edge of the sternum; the chest sunken towards the pelvis, the abdomen pendulous; the curved lower limbs, held apart and usually with one advanced in front of the other, and with both knees slightly bent; the ankles overhung by the legs, and the toes turned out.' The bones forming the vault of the cranium are generally enlarged, and there is frequently a history of larger hats being worn than formerly. The upper part of the spine is bowed and quite fixed in this position, so that, in stooping, no movement can be detected between the spinous processes. The ribs are crowded together and immoveable. The breathing, therefore, becomes entirely diaphragmatic, in a manner exactly similar to the condition which is seen in spondylitis deformans. The difference between the two diseases is, however, sufficiently distinct to make confusion impossible. In spondylitis deformans, the immobility of the spine and ribs is alone observed, combined possibly with general osteo-arthritis. But there is no enlargement or curvature of the long bones, and the skull is entirely unaffected.

On examining the lower limbs in ostitis deformans, the shafts of the long bones will be found very large and unnaturally curved, as if they had at some period of the disease yielded to the weight of the body. Other bones may also be very much enlarged, such as the clavicle, humerus, radius, or ulna, and of these the clavicles are more frequently affected than any of the others. The deformities are generally symmetrical and well-marked.

The patients oftentimes, especially at the commencement of the disease, complain of pain, which is described as rheumatic, in the lower limbs and spine. But, as a rule, there is no pain in the head, even when the skull is considerably enlarged, nor is the mind in any way altered. The general health remains unaffected, and beyond the difficulty in walking and, the breathlessness on any exertion, the disease does not cause any great distress. Life

does not therefore seem to be materially shortened.

Treatment.—There is no indication for any special treatment. Iodide of potassium, useful as it is in some chronic diseases of bone, has been found to be quite powerless to check the progress of the affection, nor does it seem to relieve the pain of which such patients occasionally complain.

OVARIAN TUMOURS.—There are several diseased conditions of the ovary which may require the aid of the surgeon, but ovarian tumour is by far the most common, and it is also the most important, because, if left to nature, it leads almost inevitably to a lingering and painful death.

Causes.—But little is known as to the causes which produce ovarian tumour. The position occupied by the ovary; its liability to displacements, which must greatly interfere with both its nerves and blood-vessels; the changes in its position which result from enlargement of the womb, or from improper retention of the contents of the bowel or of the bladder; changes in its tissues which result from the general condition of the blood during the course of the specific fevers; spread of inflammation from the peritoneum, and last, but not least, the changes it undergoes from youth to age, during the formation, maturation, rupture and cicatrization of the Graafian follicles, are all causes predisposing to disease. How it is that some of these conditions induce mere inflammatory changes in the ovary of one person, whilst in another they produce an enormous development of cysts; why these cysts differ so much in their macroscopic and microscopic appearances; and why their place is sometimes taken by a dermoid tumour, and more rarely by a solid fibroma or sarcoma, remain matters of theory and speculation.

Given the predisposing cause, such as change in position affecting the circulation or innervation of the organ; or change in the condition of the blood circulating through the ovary, and it seems very probable that heredity may have much to do with the

result, producing by the same disturbing causes different diseased conditions in different individuals.

Pathology.—Admitting the imperfect knowledge which we possess as to the causation of ovarian tumours, it is not surprising that there is great difference of opinion as to their pathology. The reader who wishes to study this subject, must refer to some of the special works in which the theories are set forth and discussed at length; here we have only space to refer to them very briefly.

Changes in the Graafian follicle are admitted by most observers to be one cause of cyst-formation. Some seem to regard the follicle as almost the sole parent of the various forms of cysts, while others give it a very secondary place, and deny that cysts formed from it ever attain any considerable size. Degenerative changes in the true and false corpora lutea, degenerative changes in the blood-vessels or in the ovarian stroma, the persistence of the rudimentary structures and elements of the foetal ovary, all have their advocates as important factors in ovarian pathology; while some of those who have been most painstaking and laborious in their investigations, believe that the commoner forms of ovarian cystomata are neoplasms of epithelial and glandular formation.

Probably each and all of these various theories have their share of truth. In an organ so remarkable in its structure and development; in its reproductive function; in the vicissitudes due to its situation and surroundings, and in its atrophy and decay; we may be prepared to find a great variety of morbid changes, rather than a repetition of any one process. The examination of a large number of ovaries in early stages of disease, and of a larger number of tumours of considerable size, with a correlative consideration of the clinical history and symptoms of the patients from whom the specimens were taken, has convinced the writer that, while all the processes referred to have their share in the formation of ovarian tumours, change of type in the cells lining the follicles, with invasion of the stroma by the resulting new-formations; colloid degenerations of the stroma, of the walls of the blood-vessels, and of the cicatrices of the corpora lutea; are—somewhat in the order in which they are given—the most common pathological processes at work in the formation of the ovarian cystomata. The more the cells lining the cysts tend to revert to immature epithelial types, and the more the cells forming the stroma of the tumours tend to revert to immature connective-tissue, the

more nearly the tumours approach malignancy. The fact that it is difficult or impossible to say which tumours are malignant and which are not, even when their tissues are submitted to microscopic investigation, should make surgeons very careful how they recommend tapping, or any operative interference short of early and complete removal of the tumour.

The dermoid tumours form about seven per cent. of the cases, and are distinctly of two kinds, benign and malignant; the former being usually associated with some of the other forms of cystic disease, are by far the most common; the latter, of which only a few specimens have been described, are nearly solid, the dermoid structures being mingled in strange confusion with carcinoma or sarcoma. Much has been written about these dermoid ovarian tumours, and the most fantastic theories have been advanced as to their origin, which is, however, probably in no wise different from that of dermoid cysts in other parts of the body, the greater frequency of their occurrence in the ovary being due to two causes—first, the special liability of the organ to originate tumours, and second, the fact that it contains cells which are capable of producing, under certain conditions, all the structures found in the body. The same causes which produce from the ordinary cells cysts or solid growths, produce from the cells which we call ova, more complex structures. The same cells which, under the stimulus imparted by the spermatozoon, produce the perfect individual, under the stimulus imparted by disease produce many or most of the structures which go to form the perfect individual, but in an imperfect form, both as to actual structures and as to their relative arrangement.

Fibromata and sarcomata are occasionally met with, but are rare, and this is not surprising, when we consider that the physiological function of the ovary is the production of cysts (the Graafian follicles). Small fibrous growths are not uncommon in ovaries in an early stage of cystic degeneration, and they appear to arise from proliferation of the cicatricial structures of the corpora lutea, and, probably, the larger specimens occasionally met with have the same origin, the tendency of the individual deciding whether a simple fibroma results from the increased growth of the cicatricial tissue, or whether some one or other of the more malignant sarcomata is produced.

Symptoms.—The early symptoms of the growth of an ovarian tumour, whether

of the cystic or solid kind, are very indefinite, and often there are no symptoms, until the growth has attained a considerable size. In some patients, scantiness of the menstrual flow, amounting, in rare cases, to amenorrhœa, will herald the commencement of disease, and pelvic pains or discomforts will lead to a vaginal examination, when the affected ovary will be found enlarged, and dislocated into the pouch of Douglas. In other cases, increase of the flow at the menstrual periods, and their prolongation, will lead to the discovery of the disease. This is especially the case in elderly women who have passed the menopause; and a return of the catamenia either irregularly or regularly, in such cases, should always lead to a suspicion of some ovarian disease, and to a careful examination of the pelvic organs. This is not sufficiently known, and many patients are made miserable by the fear that such discharge is an indication of uterine cancer, instead of being a symptom of a readily diagnosed and curable disease. Inability to walk without discomfort or pain, constipation, difficult or painful micturition, pain over the ovary, and pain or numbness in the leg on the affected side are also among the commoner symptoms, while the increase in the size of the affected ovary is still so slight that it can only be detected by the most careful bi-manual examination.

Diagnosis.—In this early stage, differential diagnosis will have to be made between organic disease of the ovary and mere enlargement due to congestion or inflammation, and it is usually quite impossible to make a certain diagnosis. Fortunately, it is not necessary for the surgeon to interfere thus early, and simple soothing treatment is equally good for either condition, and will often clear up the doubt; mere congestion or inflammation yielding to such treatment, and the ovary returning to its proper size and place.

When an ovarian tumour becomes sufficiently large to fill the pelvic cavity or rise into the abdomen, the symptoms which are present in its earlier stages usually disappear, and the time has arrived when the surgeon is called upon to make an accurate diagnosis, and decide whether the tumour shall be removed. While the tumour is still in the pelvis, it is often extremely difficult to diagnose with certainty between ovarian tumour, fibro-myoma of the uterus (especially the sub-peritoneal and pediculate forms), collections of serum, pus, or blood in the Fallopian tubes, extra-uterine foetation, serous effusion into the cellular tissue,

hæmatocele, pelvic abscess, or some of the rarer forms of pelvic tumour. The history of the case, especially as to menstrual irregularities and variations of pulse and temperature, must be carefully inquired into, without, however, giving it undue weight; for nothing is more misleading than the history of symptoms given by a stupid or unobservant patient. If the tumour be mobile, fairly separable from the uterus, the catamenia regular, and the patient free from febrile disturbance, the case is probably either ovarian or pediculate fibro-myoma, and a little patience, while watching the rate of growth and any variations in the consistence of the tumour at different times, will soon enable the surgeon to decide between them. If the tumour is fixed, and there has been fever, it is often much more difficult to decide; an experienced touch will rarely, however, in such a case have difficulty in excluding pelvic cellulitis, abscess, or hæmatocele, for in each of these there is a gradual shading off from the tumour to the surrounding tissues, and a fixing of the other contents of the pelvis, which is very different from the mere fixing by peritoneal adhesion of a tense cyst or of an elastic solid growth. The history of cellulitis, abscess, and hæmatocele is usually sufficiently marked to confirm the opinion formed by touch.

The diagnosis of the various forms of distension of the Fallopian tubes is a matter of much greater difficulty, and cases are met with in which both tubes are greatly distended with pus, forming considerable tumours, and even rising high up into the abdomen, in which absolutely no serious symptoms have been observed, either by patient or medical attendant, till the tumours have been detected by their size. In such rare cases there is no choice but to wait for further development of the tumour, or to make an exploratory operation, and as each case must be decided on its merits, it is useless to attempt to give general rules. It is necessary, however, to remember how grave may be the risk of waiting too long in a case of tubal pregnancy, of large pyo-salpinx, of pelvic abscess, or of suppuration in the uterine wall; the latter a very rare condition, but one that is occasionally met with.

When the tumour has attained considerable size, and occupies a large portion or the whole of the abdomen, the differential diagnosis may still have to be made from some of the conditions named above, such as large abscess or hæmatocele, and extra-uterine foetation, or other form of tubal cyst;

and a large number of other diseases must also be added to the list of those which may be mistaken for ovarian tumour. Solid tumours of the ovary are still more difficult to distinguish from uterine outgrowths (fibro-myomata), and some of the large soft uterine tumours give an elastic impulse so like fluctuation, that the most experienced surgeon may be deceived by it, and may mistake such a tumour for an ovarian cyst. A careful use of the uterine sound, while an assistant moves the abdominal tumour, will usually clear up the doubt, except in cases in which the uterine body is so closely adherent to, and incorporated with, an ovarian cyst, that the latter is practically a uterine tumour. In such cases an exploratory incision can alone decide.

It is rarely difficult to distinguish between ascites and cyst, but in cases in which the latter has ruptured, or has discharged much of its contents into the peritoneum through a tapping puncture, the diagnosis is difficult. In such cases it is sometimes advisable to draw off the peritoneal fluid by aspiration or tapping, and then the tumour, if present, is more easily handled and diagnosed. In ordinary cases the position of the dull area, and a careful observation as to whether the fluctuation wave extends beyond it, will decide between free and encysted fluid, but all sorts of exceptions to these general rules are met with. For example, a flaccid, broad ligament cyst will often very closely simulate ascites, the position of the dullness following the changes of position on the part of the patient; so also a cyst with its borders overlapped by adherent intestine, may readily be mistaken for free fluid, or for peritoneal fluid partially encysted. The rule usually given as to the dullness in ovarian dropsy being more to the one side than the other is, in the majority of cases, fallacious; comparatively small tumours frequently occupying a central position. In deciding whether fluid be free in the peritoneum or in a cyst, the most important point to note is, whether the line of dull percussion and the limit of fluctuation exactly correspond; if they do it is nearly certain that it is in a cyst, and changing the position of the patient, without varying the relation of the dull and clear areas, will confirm the diagnosis.

The best way to arrive at a diagnosis in a case of abdominal tumour, is to place the patient on the back with the head and shoulders well supported by pillows, the hands laid at rest on the shoulders, and the knees raised. The abdomen should then be thoroughly exposed, and the patient made to

breathe through the mouth, the lips and teeth being kept well apart. This relaxes the muscles and enables the surgeon to tell at once, by palpation, where it is soft and natural. The healthy parts should first be thoroughly palpated and percussed, because in passing from the normal to the abnormal, a correct impression of the disease is much more likely to be obtained than by the reverse process. Having carefully mapped out the abnormal structure, and noted its relations to the surrounding and healthy parts, the patient's position should be changed in various directions, and the same process repeated in each. During this procedure, anyone with experience will probably have made up his mind as to the nature of the tumour; but it will be well nevertheless to continue the investigation by excluding the possible growths one after another, till the one he has diagnosed is reached. It is undoubtedly true that the first and rapidly formed diagnosis of an experienced surgeon is often the most correct; but nothing is ever lost by care, and serious error is frequently avoided.

In deciding that a tumour is ovarian, ascites of various kinds, phantom tumours, obesity, malignant or simple enlargements of the liver; distension or tumour of the gall-bladder, solid enlargements and cystic tumours of the spleen; tumours of the omentum and mesentery, sub-peritoneal cysts; distensions, cysts, or solid tumours of the kidney, distension of the ureters, distension of the bladder; hydatids of liver, spleen, kidney, omentum, mesentery, or parietal peritoneum; accumulations (for instance, hair) in the stomach; fecal accumulations in the bowel; the various forms of extra-uterine pregnancy, hydramnios, accumulations in the Fallopian tubes, fibrocysts, and solid fibro-myomata of the uterus; peritoneal and retro-peritoneal hæmatocoele, pelvic abscess, abscess of the ovary or of the uterine wall, cysts in connection with the spinal cord; and last, but not least, ordinary pregnancy, should each and all be passed rapidly through the mind. Of course the experienced surgeon will do this almost by intuition, without the onlooker noting the steps of the process; but the student, and the practitioner who has but few opportunities for examining such cases, will make fewest mistakes and learn most, who spends some time and care over a diagnosis *by exclusion*. Even the most experienced would often save themselves from discreditable mistakes, and their patients from serious calamities, by a little more method in their examinations. All said and done,

there will still be cases of abdominal tumour which will defy the ingenuity of the most skilful, and only be certainly diagnosed by exploratory incision.

Treatment: aspiration or tapping.—Before passing to the operation for the radical cure of ovarian tumour, it is necessary to say a few words about aspiration and tapping. It is occasionally advisable to perform one or other of these operations and remove fluid from the peritoneum, in order to give temporary relief to lungs, heart, or kidneys, or to enable an abdominal tumour which is surrounded by fluid to be more accurately examined. The chemical and microscopical examination of the fluids thus obtained may throw important light upon their source, but these examinations, even by experts, cannot be trusted to alone for the formation of a diagnosis, but must be carefully compared with the symptoms and physical signs present in the case.

It has long been the fashion to advise one or more tapplings in ovarian tumour or dropsy, and to claim it as a curative operation in parovarian and broad ligament cysts; there are, however, immediate dangers attending this apparently trifling operation, and a more extensive knowledge of the nature of ovarian cysts and their contents shows that the more remote dangers are still more to be dreaded. Among the former are fatal hæmorrhage into the cyst, acute peritonitis from escape of unhealthy cyst-contents into the peritoneum; inflammation and suppuration of the cyst-wall and serious adhesions to other organs; among the latter, the growth of malignant disease in the parietes or peritoneum at the tapping puncture, or its still wider diffusion over the peritoneal surfaces. The apparently simple cysts are as likely to cause these latter disasters as those in which the malignant elements are more clearly discernible, and the parovarian and broad ligament cysts are very often the seat of a form of papilloma, which, with opportunity, readily diffuses itself over the peritoneum. When it is considered that tapping cannot cure an ovarian cyst, and but rarely cures any other, and that it exposes the patient to all these dangers, it must be admitted that the surgeon best consults his patient's well-being and his own reputation, who resolutely refuses either to tap or sanction the tapping of these cysts. As tapping of the peritoneum is not only justifiable but advisable in certain cases, and as tapping of an ovarian or broad ligament cyst may occasionally be necessary, in consequence of special complications, or of the obstinate

refusal of the patient to submit to the major operation, it may be well to say a few words about it.

If the surgeon tap with 'Listerian' precautions—and no wise man will perform the operation without them—the patient should be laid on her side with the abdomen overhanging the edge of the bed, and protected by towels or india-rubber sheeting from chilling and wetting by the spray. Then, if the fluid be in the peritoneum, a lancet should be pushed boldly through the linea alba, and a conical and blunt-ended trocar, with holes at the sides, rapidly introduced through the puncture as the lancet is withdrawn; if a cyst is to be tapped, the lancet puncture should only penetrate the skin, and a sharp-ended trocar, such as Thompson's, should be used for the cyst, as it is less liable than the lancet to wound any large vessel in the cyst-wall. When the peritoneum or cyst is empty, the trocar should be quickly withdrawn, while the finger and thumb of the left hand compress the point of puncture and prevent the entrance of air; a small pad of antiseptic dressing should then be placed over it, and a larger piece of adhesive plaster, and the patient turned on to her back, and the abdomen supported by a flannel bandage or soft towel, secured by a few safety-pins. The patient should be kept on her back for twenty-four hours, or longer in the case of a cyst, to avoid weeping from the puncture. No squeezing or pressure on the parietes should ever be allowed during tapping, or air in large quantities may be sucked in. It is quite needless to apply a sheet or a many-tailed bandage round the patient during the evacuation of the fluid if the side posture, with the head and shoulders nearly on a level with the body, be adopted. In such antiseptic tapping a good-sized trocar, from a quarter to half an inch in diameter without any tubing on it, may be used, and the canula can readily be cleared by a probe if necessary, and the entrance of a little air disregarded. If, however, antiseptic measures are not adopted, it will be safer to use the aspirator, with the finest needle that will evacuate the fluid, and the greatest care to exclude air. Even in this case the needles should be carefully oiled with carbolic oil, or other antiseptic, as the most rapidly fatal septicæmia has been known to follow the use of a dirty trocar in tapping an ovarian cyst.

J. KNOWSLEY THORNTON.

OVARIOTOMY.—The operation for the removal of an ovarian tumour has

been, from its early days, termed Ovariectomy, and though Oöphorectomy would have been a more correct description of the procedure, the old term has become so famous that it can never be discarded; and Oöphorectomy has now become thoroughly associated with a different class of operations, which have been described in so far as they differ from Ovariectomy.

Preparation of the Patient.—It is essential that the bowels should be acting regularly and well, and that the secretion of urine be free. To ensure this, mild aperients should be given for a few days before operation, and fifteen grains of citrate of potash well diluted three times a day. It is rarely necessary to restrict or alter the diet, but patients are better altogether without, or with very little, stimulant, and with red meat only once a day for some time previously. If the operation be in the morning, at nine or ten o'clock, the bowels should be well cleared over night by a simple enema, and at about five or six the patient should have a good breakfast-cup of strong beef-tea or soup, and nothing more before the operation. If the operation is to be in the afternoon, the enema should be given either before breakfast or a couple of hours before the operation, and the patient should have a light breakfast at the usual hour, and the cup of beef-tea about noon. Whether the patient has passed water or not, the catheter should be passed immediately before the operation. The best dress is the ordinary night-dress, with a short flannel jacket, and stockings on. The room where the operation is to be performed should be arranged while the patient is in another, and the instruments should be covered up, so that she does not see them when she comes in. It is far better for her to walk quietly into the room and lie down on the operating table before the anæsthetic is given; but only the surgeon, the anæsthetist, and the nurse should be present till she is unconscious. This plan not only saves time, but avoids the necessity for carrying the patient from the bed to the table during narcotism, which is always objectionable, and especially so in cases with a greatly distended abdomen, and impeded circulation and respiration.

The particular anæsthetic must be left to the taste of the individual surgeon. Chloroform, given by a Junker's inhaler, answers well in most cases.

Preparation of the Room, Instruments. Sponges, &c.—The room should be light, airy, and quiet, and should be thoroughly cleaned the day before, and all dust should be wiped away with a damp cloth, but there

is no necessity to remove carpets, curtains, &c., and make it bare and cheerless.

The patient should be laid on her back, the head and shoulders well supported by an inclined plane of pillows, and the feet towards the window. The table should be long enough to hold her comfortably, not too wide—about 2 feet, and high enough to avoid much stooping on the part of the operator. When a single ordinary table is not at hand, two light deal dressing-tables answer very well, the lower one placed slantways across the window, and the upper one across its upper end, so that the two form the letter L placed upside down towards the window. The legs of the tables should be tied together to prevent their slipping apart, and the patient, when nearly unconscious, should be secured to them by a broad strap firmly fastened just above the knees, and by soft leather wristlets with a connecting strap under the table. In the window stands a small oblong table large enough to hold the spray-producer, the instrument-trays, and the dressings.

The operator stands on the right side of the patient, with his right hand within easy reach of this table, so that he can take up each instrument quickly as he requires it; this is much better than trusting to an assistant or nurse to hand things, for no two brains can work like one, and it is often important to take the right thing without loss of time. The chief assistant stands opposite to the operator, and, at his right hand, on the projecting upper part of the operating-table, is placed a large basin full of warm 1-40 carbolic lotion with the clean sponges in it. The nurse stands beside this basin, and squeezes out the sponges as they are wanted. No towel should ever be used for this purpose, and the sponge should touch nothing but the hands after it leaves the lotion. The anæsthetist stands at the patient's head, and if another assistant is wanted (which is rarely the case) he stands at the operator's left hand. The operator should have a basin of warm 1-40 lotion, with a sponge in it, near him on a chair. The spray bottle should be filled with 1-20 lotion, the instrument trays with warm 1-40 lotion, so that all the instruments are well covered. Ordinary tin pudding-trays, 14 inches long by 6 inches wide, and 2 inches deep, will be found most convenient. Two of these will hold all the instruments necessary for the most complicated abdominal section. The instruments should all be arranged each in its own place in the trays, and the lotion poured over them half an hour before the

operation begins. The silks used for ligatures and sutures should be soaked in 1-20 lotion for at least an hour before use. The nurse who stands by the sponge-basin holds an empty basin for the dirty sponges, takes them and washes them well in a large footpan of warm water, and then replaces them in the 1-40 lotion, from which she or the assistant squeezes them, and hands them to the operator.

The preparation of the sponges is very important. New sponges require much knocking or beating in a pillow-case while dry, and many washings in warm water, or in water slightly acidulated with hydrochloric acid to get rid of the sand. They are then dried, and, if no sand can be knocked out of them, they are placed in 1-20 carbolic lotion for twenty-four hours. After they have been used, they are washed in warm water with common washing soda, to remove all blood and grease, then several times in plain warm water, then in 1-10 solution of sulphurous acid; this whitens, softens, and disinfects them, and after being well wrung out of it they are ready for use. They should be placed in the warm 1-40 lotion from which they are used, at least half an hour before the operation.

The abdomen of the patient should be well washed with warm 1-40 lotion by the nurse before she comes into the room, and covered with a moist napkin wrung out of the lotion; this is covered with a piece of mackintosh, and kept in its place by the flannel bandage to be used after the operation, pinned with three safety-pins. This flannel bandage is made of fine flannel lined with soft calico, the latter sewn over the edges all round, so that the flannel does not touch and irritate the skin. It is used all through the progress of the case, to keep the dressings in place, and give the parietes firm support.

When the patient is unconscious, a large piece of mackintosh, with an oval window cut in it, the edges of the opening smeared round with carbolised adhesive plaster, is applied to the abdomen. This apron should be large enough to cover the whole patient, and keep everything clean and dry. The abdomen and outer surface of the apron, the hands and arms of the operator and assistants, are well wetted with 1-40 lotion, without any after-drying, and the spray is turned on.

The instruments necessary for an ovariectomy of average difficulty are: two sharp, straight bistouries, and one with a probe point, a director, Adams's eye-hook, a pair of ordinary artery catch-forceps, twelve or

more pairs of Wells's small pressure-forceps, a vulsellum, two pairs of Nélaton's cyst-forceps, a long-bladed temporary clamp, two curved perineum needles in handles, one long straight needle (five or six inches long), a pair of smooth-ended uterine polypus-forceps for passing the sponges into the pelvis, flanks, &c., a pair of blunt-ended scissors curved on the flat, a scissors-handled needle-holder and twenty straight needles threaded in pairs on No. 1 silk, eighteen inches long, for the abdominal sutures, and a large cyst-trocar; also No. 0 or 1 Chinese silk for fine ligatures, and No. 3 for tying the pedicle; these should be wound on reels, and should have been in soak in 1-20 phenol lotion for at least an hour.

Each instrument, as it is used, is taken out of the solution in the trays, and replaced in them when it is done with, or till it is wanted again. It is a common thing to see bloody instruments laid about on blankets, towels, &c., quite out of range of the spray, then taken up and used again without washing in the lotion, and the operator is indignant if he is told that he is careless, and is surprised if his case does not run an aseptic course.

Operation.—The incision through the skin and the abdominal wall, down to the fat over the peritoneum, should be made rapidly with a few bold sweeps of the knife; then, the assistant sponging the wound, each bleeding point is secured by a pair of pressure-forceps. The peritoneum is then to be opened, and this is easy enough in an ordinary case, as the tumour can be seen through it; but where there is adhesion more care is required, or the cyst-wall may be incised, or omentum, intestine, or bladder injured. For picking up a delicate peritoneum Adams's eye-hook will be found very useful, and it is a far safer instrument to use for this purpose than the ordinary artery-forceps, which is often employed, as with it the omentum or intestine is very likely to be picked up and incised along with the peritoneum. As soon as the peritoneum is opened to the extent of the external incision, the cyst should be tapped and emptied. Frequently the adhesions are first separated, but this is bad practice, because if they are separated while the parietes and cyst-wall are both stretched by the fluid, all the little vessels in them bleed, and very serious hæmorrhage may occur out of sight during the subsequent emptying of the cyst; whereas if the cyst be first tapped, the contraction of both parietes and cyst-wall closes the smaller vessels. Moreover, the cyst, when flaccid,

can be separated from adhesions bit by bit, each vessel being secured by temporary pressure-forceps or by permanent ligature, as it is torn or cut. If there are more cysts than one to empty, the trocar may be pushed on from the first into the others till they are all emptied, but great care must be taken not to push it through the cyst-wall against intestine. When the tumour is more solid, the trocar should be removed, its hole of entry enlarged, and the hand introduced to break down the septa.

As soon as the tumour is sufficiently reduced in size by one or other process, the operator should explore the peritoneum round it with his hand, to see if there are adhesions, and to learn the seat and character of the pedicle. Before doing this, he should carefully wash his hands in the basin of lotion by his side; for, if his hand has been in the cyst, he may carry cells into the peritoneum, which will set up new growths there. The frequent washing of the hands during an operation of this kind is also important, to avoid the introduction of blood, &c., into the recesses of the peritoneum. If there are no adhesions, the cyst should be slowly and carefully extracted till it is all outside, and the pedicle fully exposed, its place in the abdomen being taken by a large, flat, soft sponge, freshly wrung out of the warm lotion.

The operator now grasps the pedicle between the left thumb and forefinger, gathering in his grasp all the large veins in its outer part, but avoiding the Fallopian tube; manipulating the pedicle between the nails of the finger and thumb till he gets a small spot clear of any vessel, he transfixes with an ordinary, fine, short, straight needle, threaded with a single No. 3 Chinese twist ligature, and with this ties all the veins (pampiniform plexus) in the outer part of the pedicle. If the patient be young and full-blooded, it is well to pause a few minutes and let the arterial blood go on pumping into the cyst till it is well injected; this is a neat and cleanly way of bleeding the patient if it seem advisable. If, on the other hand, the patient be already very weak and anæmic, this *outer-edge* ligature should be applied last. The *outer-edge* ligature being tied, another non-vascular spot in the pedicle is manipulated between the finger and thumb, and through it a long-handled, curved perineum-needle, armed with a double No. 3 ligature, is passed, the outer loop is tied in the groove formed by the *outer-edge* ligature, but includes a greater thickness of the pedicle; care being taken that the ligatures interlock, the inner

loop is then also tied, and it includes the Fallopian tube and the chief arteries. In broad, thick pedicles, two or three such transfixions may be necessary, and in this case one loop should be tied, then the untied ligature is re-threaded into the needle together with a third silk, and they are passed through the pedicle; the second loop of the first transfixion is then tied, care being taken that it locks with the last silk which was introduced with it, and thus a perfect chain is formed, and slipping of ligatures is impossible, while bleeding from the transfixion punctures is also prevented. The pedicle on the distal side of the ligatures is now seized on its inner and outer borders with a couple of pairs of pressure-forceps, and the tumour is cut away about three-quarters of an inch from them; a shorter stump is not safe, and a longer one being imperfectly nourished is likely to lead to trouble, such as adhesion to intestine, &c., or even to inflame and suppurate or slough.

After the tumour is cut away, the assistant holds up the stump by the two pairs of forceps, and a separate No. 3 ligature is tied round the whole for greater security. These pure silk ligatures absorb more slowly, but as perfectly, and with quite as little irritation as catgut. If the operator prefer to use the actual cautery, the tumour should be held up by the assistant, while Baker Brown's cautery-clamp, with the ivory non-conductors downwards, is applied and firmly screwed up; the tumour is then cut away, leaving a good inch of tissue outside the blades of the clamp. This stump is then slowly burnt away with the cautery-irons at a very dull red heat; when it is burnt off level with the blades they are unscrewed and slowly opened, and if sufficient time and care have been taken, the part between the blades will be found in its whole thickness decolorised and translucent, like a piece of horn; if any points bleed the clamp must be screwed up, and the irons reapplied, or it may be necessary occasionally to ligature a vessel or two. When released from the clamp, the stump should be allowed to drop quietly back into the pelvis, and care should be taken not to disturb it in any after sponging which may be necessary. The cautery needs more time and care than the ligature, is not nearly so universally applicable, and requires greater experience in its use; but, where it can be used, results are excellent, and as a theoretical method it is certainly perfect. It should never be used after ligature by the ordinary method, as it destroys the vitality

of the distal part of the stump, and may lead to sloughing. No directions need be given for applying the clamp, as that is a clumsy contrivance which has deservedly passed into obscurity.

Cases are met with in which the base of the tumour is so situated between the layers of the broad ligament, or so pushes its way under the peritoneal covering of the uterus, or of the pelvic floor, that cautery and ligatures are alike inapplicable, or at least ligatures can only be applied after much previous enucleation. When this is the case, an incision should be made through the peritoneal capsule of the tumour, and careful enucleation practised with the fingers. It is well, if possible, so to direct this process as to isolate, at an early stage, the parts of the broad ligament which would form the pedicle in an ordinary case, and then to transfix and tie them in the usual way. After this the chief blood-supply of the tumour is under control, and the rest of the enucleation may be more rapidly and boldly made. Shreds of capsule which bleed should all be secured temporarily in pressure-forceps, and ligatured with or without transfixion, after the tumour is completely shelled out. Usually, the capsule falls together and no oozing occurs, but sometimes this is troublesome from a large surface, and Paquelin's cautery, or solid perchloride of iron, may be applied. The latter is, on the whole, the most satisfactory, if applied with the precautions to be given hereafter in describing its use for oozing from adhesions.

In performing these enucleations, the operator must always bear in mind the fact that the capsule is often the pelvic parietal peritoneum, and that he is consequently brought into dangerously close relations with bladder and ureters, rectum and sigmoid flexure, or cæcum and appendix vermiformis (the latter is very frequently adherent in these cases, and, as it bleeds very much when torn, requires careful handling, and often repair with a fine needle and silk). The large iliac vessels are also occasionally incorporated with the capsule.

When much enucleation is required, it will be necessary to have many more pairs of the small pressure-forceps in the trays, and two pairs of Wells's large curved pressure-forceps, two pairs of the same straight, and a few pairs of the square or T-shaped forceps introduced by the writer, will be found very useful. The above instruments, together with assorted sizes of Keith's glass drainage-tubes, with pure rubber sheet for

fixing over them, and a Wells' tapping trocar or a small aspirator, and some No. 4 Chinese silk ready soaked, should always be at hand for a specially difficult case.

If there are extensive adhesions to parietes, omentum, mesentery, intestine, or other viscera in the case of an ordinary pediculate cyst, it is better to separate them bit by bit as the cyst is extracted, applying pressure-forceps to the bleeding points, and protecting omentum or bowel by towels wrung out of warm lotion. Then, after the tumour is entirely removed, the adhesions can be dealt with. In some few cases this method may be advantageously departed from, and the pedicle ligatured in two places and divided between the ligatures, before the adhesions are separated.

Adhesion to bowel or other viscus, which is so firm that it cannot be separated without tearing, should be treated by cutting a piece of the tumour out, and leaving it adherent till the rest of the operation is completed; when it should be carefully scraped and pared down as closely as possible, in order to leave nothing but the peritoneal and fibrous coat, and to avoid epithelial new-growth.

In some rare cases, it will also simplify the extraction of the cyst if it be seized from within and turned inside out; but the cases in which these special manoeuvres are useful can only be learnt by practice.

As soon as the pedicle is secured, the pouch of Douglas and anterior *cul-de-sac* should be sponged out, and the flat sponge changed for a clean one. The adhesions should then be dealt with. If there be much torn omentum, which has been adherent to the tumour, it is well to secure the whole of it by a chain of fine silk ligatures some little distance above the torn parts, and cut all away; this saves time, and omentum which has been closely adherent is very likely to be infected by cell-growth from the tumour, and is better removed, as it may be the seat of recurrence of a malignant growth. The bleeding points in the parietal peritoneum should be secured with fine silk ligatures, applied, as far as possible, with a fine needle passed under the mouth of the vessel; oozing surfaces may be touched over with the cautery (Paquelin's), or with perchloride of iron. If the latter be used, the surfaces to be touched should be dried with a sponge, then a small sponge, well wrung, should be smeared lightly with the solid perchloride, and firmly pressed against the oozing surfaces till the oozing stops; a large, flat sponge should be spread under

the surfaces thus treated, to prevent any of the acid serum, which runs away immediately after the application of the iron, getting on to the intestines. Oozing surfaces in the pelvis are treated in the same way, the intestines being first drawn out of the way and protected by sponges. Sometimes, tincture of iodine will answer, but its action is not so powerful as that of the iron. Mesenteric and intestinal adhesions should be secured by transfixion with fine silk, and sometimes a bleeding surface may be treated by running a fine silk in and out through the peritoneal coat, and tying it up like a bag's mouth. If the intestine or bladder be wounded, the wound should be sewn up by a fine, continuous silk suture, introduced through the peritoneal coat so as to invert the peritoneal edges. When all bleeding has ceased, the peritoneum should be again carefully sponged out, special care being taken to cleanse the pelvis, the anterior *cul-de-sac*, and the loin pouches. The pedicle is then drawn up and examined, and the forceps which were placed on it just before the tumour was cut away, are removed.

The flat sponge being still in, the sutures are introduced, straight needles about two and a half inches long, threaded at each end of a No. 1 Chinese twist ligature eighteen inches long, being used, and introduced from within outwards with the aid of the needle-holder. Each needle is passed just through the edge of the peritoneum, and then carefully through all the various structures forming the abdominal wall, and out through the skin about a quarter of an inch from the edges of the incision. The sutures should be introduced a little more than half an inch apart, the top and bottom sutures taking up the angles of the incision in the peritoneum. When the sutures are all in place, a small sponge is passed into the pelvis beside the pedicle, and, if it comes out dry and clean, the flat sponge is withdrawn, and the sponges and small pressure-forceps are carefully counted. The number of forceps and sponges in use should always be known, both by operator and nurse, before the operation, and no sponge should ever be torn by anyone during its progress.

In tying the sutures, great care should be taken to bring the skin edges accurately together, and they should not be tied too tightly, or a thin and puckered cicatrix will result, and the danger of ventral hernia from a weak scar be increased. A pad of carbolic gauze, six or eight layers thick, and large enough to overlap the edges of the incision an inch all round, is now

applied, the surface next the wound being first wetted with the lotion; over this two or three similar larger pads, and then one with a piece of pink mackintosh under its outer layer; this outer dressing should not be broader than four inches, and long enough to overlap the top and bottom of the wound by about two inches. Straps of adhesive plaster are then applied over the whole abdomen; they should be from one and a half to two and a half inches broad, and long enough to support both loins well. If the abdomen has been greatly distended, cotton-wool pads are applied over the dressing but under the strapping, to fill up the hollows and give firm elastic support. A folded towel is applied outside the plaster to overlap the lower edge of the dressing, and form a firm support to the wound, and over this the flannel bandage, already described, is pinned. The patient is then carefully lifted into bed and laid on her back, the head and shoulders well supported by an inclined plane of pillows, and a good firm pillow placed under the knees. The bed should be guarded across the centre by mackintosh and a many-fold draw-sheet.

After-treatment.—The temperature is taken in the vagina, and the pulse noted; as soon as the patient rouses up and begins to feel pain, twenty drops of laudanum in an ounce of water are injected into the rectum, and this injection is repeated two, or perhaps three, times in the first few hours. If the weather be cold, a hot bottle is placed at the feet. The patient should be lightly but warmly covered, a single blanket next the night-dress, then the sheet, and two, three, or more blankets over this according to the season. For the first twenty-four hours or more, if there is sickness, nothing is given by the mouth but little pieces of ice, or a teaspoonful of tepid water, or plain soda-water. About six hours after the operation, or sooner if the patient be very weak, three ounces of strong beef-tea are injected into the rectum. The beef-tea should be made without salt, and injected just warm enough to be liquid. This injection is, in ordinary cases, repeated every three hours (every two if the patient be very weak), and every six hours twenty drops of laudanum are added. Before each injection, the female pipe of a Higginson's syringe is placed in the rectum, with the bottom of an ordinary soap-dish under it, so that the flatus and refuse may pass away; it remains in ten minutes, and then the fresh injection is given. The injections are continued in this way for the first few days, and gradually stopped as the

patient begins to take sufficient nourishment by the mouth.

When all chance of sickness is over, a little milk and soda-water (equal parts) is given each hour, then a little bread and milk; then, if these are well borne, a little clear beef-jelly with bread, and about the third or fourth day a cup of weak tea, with bread and butter, night and morning, and a little boiled sole for dinner. Then, gradually, chicken, minced chop, &c., &c. If sickness or retching is troublesome, a tumbler of water, as hot as it can be drunk, sometimes with the addition of a teaspoonful of sal volatile, should be given. If there be peritonitis, with bilious or dark vomiting in quantity, a long red rubber rectum-tube should be passed into the stomach, and a thorough washing out with warm water, or warm water slightly carbolicised, made at intervals of from six to twelve hours, till the fluid ceases to accumulate. Liquid nourishment and stimulants, if necessary, may be given between the washings out, and much will be absorbed till the stomach begins to distend again. In some cases, large quantities of dark green, purple, or black fluid can be got rid of in this way, and a patient's life saved. In ordinary cases, the temperature rarely rises above or even to 101° F.; but if it should rise much above this, especially if the pulse quicken also, some pounded ice, tied up in a piece of mackintosh, should be kept on the head till the temperature falls to normal. If more severe hyperpyrexia is present, the india-rubber coil ice-water cap should be applied. In either case, when once used, ice should not be taken on and off, or serious brain-mischief may be induced. Ice should never be put on after the operation, till the skin is acting well.

Rapid rise of temperature before the skin acts is rarely of consequence, but if it continue with a freely acting skin, it should be checked. In very rare and extreme cases even the ice-water cap is not sufficient, and it will be necessary to pack the limbs or the whole body, except the abdomen, in cold, wet sheets. If the cold pack is applied, the arms should first be wrapped in wet towels, then iced water should be squeezed over them from a sponge as they dry, and if the temperature still rises, the legs, and, if necessary, the trunk, should be treated in the same way. The temperature should be taken at least every hour in the vagina in these cases, as the cold sometimes causes great and sudden depression. If there be any trouble in the downward passage of the flatus, or any threatening of intestinal ob-

struction, a mixture of *Liq. morph. hydrochloratis* ℥x. and *Liq. atropiæ* ℥ij. in a teaspoonful of water, should be given every three or four hours till the distension is relieved.

If the refuse from the rectal feeding be offensive, or if too much comes away, a couple of grains of quinine, in a dessert-spoonful or table-spoonful of port wine, should be added to each injection. Septic mischief may result from the retention of a quantity of putrid beef-tea in a rectum which has become sore and irritable.

In all ordinary cases, the dressing should remain undisturbed for a week or eight days; it should then be taken off, the wound moistened with warm 1-40 lotion, and all the sutures be removed. A smaller gauze dressing, with the same method of strapping, is then re-applied for another week, at the end of which time the wound will be found firmly healed, if care has been taken in approximating the skin-edges. Straps, six inches long, are then all that is necessary, and these should be changed every week or ten days by the patient after her return home, for at least two months, to secure a thoroughly firm, linear cicatrix, and avoid all chance of ventral hernia.

The catheter is generally necessary for the first few days, and with some patients till the bowels have acted, or till they can sit up. Some patients will pass their urine almost from the first. The nurses should be made to use silver catheters with a stilette, and to keep them scrupulously clean, and also in cases in which there is any vaginal discharge, to sponge with a little weak carbolic lotion before passing the catheter. Almost all fresh nurses produce cystitis by clumsy use of the catheter, and it is a great misery to the patient, often leaving an irritable bladder for weeks after everything else is well.

The bowels will usually remain quiet for a week, but may be moved a day or two earlier in some cases. The nurse should pass her finger into the rectum as soon as the patient feels any uneasiness, and if there are hard feces, she should inject 4 oz. of warm olive oil, leave it in for four or five hours, and then give a simple water, or soap and water, enema of a pint and a half; it is better to give two or three small enemata till the bowel is clear, than to over-distend it at first. After the bowels have been once cleared, an enema should be given every second morning till they act of themselves.

The patient should have a good fitting elastic abdominal belt, and this should be

put on at the end of the fortnight, after the second dressing, when she may be allowed to get on to the couch. Hospital patients are generally quite well enough to go to a convalescent home from the eighteenth to the twenty-fourth day after operation. Sometimes, convalescence is retarded by phlegmasia or thrombosis, just when they first begin to move about. This is often a cause of a good deal of pain, and sometimes of sharp rise of temperature; it rarely troubles them more than a few days or a week, if they are kept quiet in bed with the leg rolled up in cotton-wool. It is good for the patient to remain on her back for the whole of the first fortnight, and until she gets on to the couch; but, if the back be tender, she may be allowed to lie over on the side, well supported with pillows, a little earlier. It is, of course, impossible to discuss at length the treatment of the complications which may arise. In aseptic cases they will be few, and opium and ice will be found all-powerful in subduing them.

In cases operated upon antiseptically, drainage will not be necessary in more than two per cent. When it is thought advisable to use it, Keith's modification of Koeberle's glass tube answers best. It should be long enough to reach to the bottom of the pelvis, and just protrude from the lower angle of the wound, with its mouth covered with a carbolised sponge; or it may be put through a hole in a small pure rubber sheet, the antiseptic dressing being applied closely round its mouth, and the sheet filled with carbolised sponges and fastened up. Whichever plan is adopted, it will be necessary to expose the mouth of the tube, under the spray, every six or eight hours at first, and then night and morning, and clear it with a glass syringe, to which a piece of red rubber tube is attached. When once introduced, it should be kept in till the serum from it is colourless and ceases to overflow into the sponge. It is a good plan to introduce a suture across the tube-opening at the time of operation, and leave it loose, to be tied up when the tube is withdrawn, otherwise the tube-opening causes a weak place in the cicatrix, which is liable to lead to ventral hernia.

In cases operated upon without antiseptics, the tube will be much more often required, probably in from ten to fifteen per cent. of any ordinary run of mixed cases (i.e. simple and difficult). It must not be forgotten, however, that the tube, though useful for the escape of material which may putrefy and cause trouble, is

also a distinct source of danger, especially in non-antiseptic hospital cases, for it forms an open channel through which infective particles may find their way into the deepest recesses of the peritoneum. There is another element of danger in its use, and that is the matting of intestines round it, leading to obstruction, either immediate or remote.

If there is reason to suppose that an accumulation of putrid serum has gathered in the peritoneum, in any case where the tube has not been used, it may be advisable to puncture the pouch of Douglas through the vagina, with a Cock's trocar, and leave the canula in, retained in place by a Wells' spring; or a suture may be taken out at the lower angle of the wound, and a grooved director pushed down into the pelvis, behind the uterus. These proceedings are, however, rarely successful, as the blood-poisoning has generally gone too far before the accumulation is suspected, or before the surgeon can make up his mind to interfere.

When a patient, after ovariectomy, leaves the surgeon's care, she should be cautioned to keep quiet during the first menstrual period, as hæmatocoele from the pedicle is occasionally met with. The mention of this recalls a subject which may be named here, though it would more properly have found a place in the preparation of the patient for operation. It has long been the fashion to advise that ovariectomy, and similar operations on the uterus and its appendages, should be performed shortly after the conclusion of a menstrual period. This is a mistake; the best time to operate is from a week to a few days before the period comes on. A little consideration will show that this is theoretically as well as practically advisable. A metrorrhaxis, or false period, frequently follows the operation within twenty-four or forty-eight hours, this being especially the case when both ovaries are removed, and when the ligatures are tied very close to the uterus (i.e. on a short pedicle). Just before this metrorrhaxis comes on, there is often pain, fever, and general upset; but as soon as the flow is established, a normal pulse and temperature are common. Theoretically, the nearer the proper time for menstruation, the more likely it will be to come on without disturbance, and this is found to be true in practice. Patients may even be operated upon during menstruation, without affecting the flow; but this is not advisable for many reasons. Young and middle-aged women, who have had both ovaries cleanly removed, rarely menstruate

again, but some have an occasional metrostaxis, which is preceded by a good deal of general constitutional disturbance. The majority of them also entirely lose sexual appetite; indeed, the exceptions are so rare that it may be presumed that, in these cases, a small portion of ovarian tissue has been left behind, or a third ovary has escaped notice. Patients who have had both Fallo-

pian tubes cleanly removed, and the ovaries left behind, continue to menstruate regularly. J. KNOWSLEY THORNTON.

P

PALATE, Diseases of the.—The palate, owing to its structural continuity with the alveoli and gums in front, and its connection posteriorly with the tongue and pharynx by means of the pillars of the fauces, is liable to implication by the extension of disease from these parts; whilst, on the other hand, morbid processes originating in the palate may spread to the neighbouring portions of the mouth, fauces, or pharynx.

It is necessary to recollect that the palate, with the posterior pillars of the fauces, constitutes a septum between the nasal and buccal passages, which by the contraction of the palato-pharyngei becomes complete during the act of deglutition, and then cuts off all communication between the two cavities; and that its structural and functional integrity is essential for perfect articulation, suction, and deglutition. Hence, the chief symptoms induced by lesions of the part are usually dependent upon impairment of these physiological acts.

The diseases of the palate are—(1) congenital malformations (see CLEFT PALATE), (2) inflammation, (3) ulcers, (4) necrosis, and (5) tumours.

1. **INFLAMMATION** may consist of a simple phlegmon of the soft parts; or, in the case of the hard palate, may involve the periosteum and bone.

(a) *Phlegmonous inflammation* is rare except as a result of extension from the tonsils and other adjacent parts. In the velum palati it is accompanied by considerable swelling; but this sign is absent in the hard palate, owing to the intimate adherence of the mucous membrane to the bone. It may terminate in abscess.

(β) *Syphilitic Angina*, which coincides in period with the early cutaneous manifestations, is usually most marked in the palate. It appears as a diffuse redness, with more or less swelling of the mucous

membrane of the fauces, and is often of so little intensity that it may be entirely unnoticed by the patient; but occasionally it assumes a parenchymatous form, and may lead to abscess-formation or even to sloughing of the soft parts. It may also become chronic, lasting two or three months.

(γ) *Osteo-periostitis* may arise from traumatic causes, extension of alveolar inflammation, or from syphilitic or tubercular cachexia. The disease is indicated by a local swelling, at first hard, then fluctuating; and there is more or less pain (slight in the syphilitic form) in mastication and deglutition. Should abscess supervene, the bone usually perishes, and its bared surface may be felt through the opening of discharge. The separation of the sequestrum may leave a temporary or permanent fistulous communication between the mouth and nose.

2. **ULCERS.**—The principal forms of ulceration of the palate are of syphilitic, tubercular, or epitheliomatous origin. Simple ulcers are rare except as a result of local injury, and present no special features of interest.

Syphilitic ulcers may be superficial or deep, as in the rest of the bucco-pharyngeal tract. See STOMATITIS. The former is common in the early secondary stages of the disease; the latter belongs to the tertiary period, and results from the breaking down of a gummatous infiltration. The deep ulcer appears late, from five to eight years after the primary lesion, and is generally single. If situated upon the hard palate it is nearly always central, and involves the bone; if the soft palate be the point of attack, great destruction and deformity may result, sometimes complicated with adhesions to the posterior wall of the pharynx. In rare instances the tertiary ulcer may spread to the base of the cranium. The sore has the usual characters.

Tubercular ulcers are most frequently developed in childhood. They usually reach the palate by extension from the posterior pillar of the fauces, and are associated with tubercular disease elsewhere. The lesion generally makes its first appearance in the form of small tubercles, which project slightly above the surface:—these break down into a number of erosions which soon fuse into an irregular ulcer of little depth characterised by festooned borders, and a yellowish base covered with pale granulations. The sore thus formed tends to travel slowly in a serpiginous course, but seldom leads to serious destruction.

Epitheliomatous ulcers are excessively rare as primary lesions of the palate, but may extend to the part from the gum or tonsil (q.v.).

3. TUMOURS.—In addition to inflammatory, tubercular, and gummatous swellings, the palate is subject to a considerable number of true tumour-growths, which may be briefly enumerated as follows:—

Cysts, mucous and dermoid; Fibroma; Enchondroma and Osteoma; Myxoma; Lipoma; and Adenoma.

The glandular tumour is by far the most common of the palatal neoplasms. It is often found upon the hard palate, generally implicating its lower wall on one or other side, and may reach the size of an egg or even attain larger dimensions. It is soft and elastic to the touch, painless and insensitive, and causes no symptoms beyond the inconvenience attached to its encroachment upon the buccal cavity. Structurally it follows the type of the salivary glands; it is invested by a capsule, and is united to surrounding parts by a somewhat loose connective tissue. The glandular elements of the soft palate may undergo hypertrophic changes, by which the thickness of the velum becomes greatly augmented, a condition which is probably analogous to the enlargement of the lip in strumous children.

Erectile tumours are almost confined to the hard palate, but the velum may be implicated by a nævus extending from the inner surface of the cheek. Papillomata, in the form of small, usually pedunculated growths, are not very infrequent, and are most commonly attached to the posterior border of the soft palate and to the uvula.

Sarcoma is rare. The tumour is usually of the round-celled variety, but in one instance was found to consist of fusiform and myeloid cells.

Epithelioma is rarely developed primarily in the palate, but may involve the

part in association with the tonsils and nasal fossæ, &c. The thyro-hyoid and carotid glands become affected at an early period of the disease.

Treatment.—The treatment of inflammatory and ulcerative affections of the palate should be conducted on the same principles as in other parts of the mouth. *See STOMATITIS.* Of the tumours, the cysts, fibromata, enchondromata, myxomata, and lipomata, all of which are rare, may ordinarily be removed with the knife. Adenomata are, as a rule, most easily enucleated with the finger-nail or curette. Erectile tumours are best attacked by means of coagulant injections or galvanopuncture. Papillomata may be cut off with the thermo-cautery scissors. Sarcomata, if not too extensive, may be excised. Epithelioma and carcinoma are seldom met with in a condition susceptible of any but alleviative treatment; but if small may be removed, or their destruction may be attempted by means of the galvanocautery.

The chief danger attached to the operative treatment of palatal tumours is the ingress of blood into the trachea, an accident especially liable to occur when the patient is under the influence of chloroform or ether. Fortunately, the surgeon is now provided with a local application which renders it possible to dispense with general anæsthetics in many cases. The use of a solution of cocaine painted upon the surface, or injected into the substance of the part to be subjected to operation, will commonly allow the painless removal of the growth while the patient retains consciousness and is able, in some degree, to guard the air-passages. Should it, however, be absolutely necessary to induce general anæsthesia, or should the danger of asphyxia threaten despite the absence of unconsciousness, the operation may either be performed while the head hangs down over the end of the operating table, so that the blood passes into the nares; or the back of the fauces may be plugged after a preliminary tracheotomy.

PALMAR ARCH, Wounds of the. Special interest attaches to wounds of the palm on account of the liability to injury of one or other of the palmar arches, the superficial being that most frequently

involved. When the wound is extensive, it may be possible to secure the divided ends of the vessel, but the most serious difficulty is met with in the cases of small punctured wounds dividing the artery, such as are caused by a penknife or piece of glass. If the puncture is found to run in a direction towards the artery, and if constant or recurrent hæmorrhage ensues, as the nature of the parts does not allow of the enlargement of the wound, other methods of stopping the hæmorrhage must be resorted to. Of these, pressure systematically applied will generally be attended with success. The wound having been cleansed, and all bleeding being temporarily arrested by compression of the brachial artery, the fingers should be separately bandaged, and a graduated compress carefully applied over the wound. The bandage securing this should be carried up the arm, and should also fix two oblong pads placed over the radial and ulnar arteries, so as to limit, but not entirely check, the amount of blood passing through them. A splint should then be applied to the forearm, and the fingers so bent over it as to relax the palmar fascia. The limb should be raised as high as possible. The patient lying in bed, this can be effected by pillows, or better, by a pulley and counterpoise. No hæmostatic solutions should be used, on account of the danger of sloughing of the tissues. If, after a fair trial, these measures do not succeed in restraining the bleeding, it will be necessary to ligature the brachial artery in the arm, or the radial and ulnar in the forearm. The choice of operation should be guided by carefully ascertaining whether digital compression of the two latter vessels entirely controls the hæmorrhage. If there be any doubt on this point, it is wiser to ligature the vessel in the arm, since the interosseous and median arteries may largely supplement the vessels of the forearm.

A *palmar aneurism* is formed when the vessel is divided or punctured, and remains open after the superficial wound has closed. The blood is poured out into a circumscribed cavity, which is limited by lymph effused from the surrounding tissues; and the tendency of the effusion is to spread either towards the ball of the thumb or towards the ulnar side of the palm. The symptoms are identical with those of traumatic aneurism in other parts, but the treatment here should not be to lay open the sac and ligature the divided ends of the vessel, but to apply pressure as above directed, and this measure will in most cases effect a permanent cure. Should it

fail, however, it will be best to apply the same rule as in the case of wound of the arch, to determine the selection of the artery to which a ligature should be applied.

PANOPHTHALMITIS. See EYE, General Examination of the.

PAPILLOMA.—Under the general designation of papilloma are comprised numerous conditions of the skin and mucous membranes, which, if of the skin, are usually of a dense, horny, non-sensitive character; or, if of the mucous membrane, are often highly vascular and sensitive. Among the affections comprised in these two groups are included corns, moles, common warts, condylomata, mucous tubercles, and verrucæ of the genital organs, which may be regarded as vegetations or excrescences arising, for the most part, from the stimulation of acrid discharges or other less pronounced forms of irritation. All are forms of hypertrophic papillary structure, which may subside on the cessation of the cause, or are readily curable.

It is a question whether the term 'papilloma' should be given to these, or should not rather be reserved for the comparatively rarer outgrowths which may be found on the skin and mucous membranes, such as the horny excrescences of the scalp, and the coarse, fringe-like vegetations seen in the axilla, flexures of the groins and scrotum, or around the anus; or for those similar growths on mucous surfaces which occur in the mouth and larynx, or as the so-called villous tumour of the bladder, and the highly vascular polypoid-looking growths which cover the rectum.

Cause.—Excepting, of course, congenital moles, papillomatous affections are all alike directly due to some form of irritation—usually some stimulating secretion—which may be of a specific nature—or they may be the result of pressure, as in corns, or of friction of neighbouring parts. In the majority of cases the source of irritation is at once apparent, but in others it is not clear, and one may find only some predisposing cause, such as residence in the tropics or an abnormally moist skin.

Pathology.—All papillomata are essentially hypertrophies, and, since a papilla has a definite structure, and is not merely

a tissue, such homogeneous texture as is seen in lipoma and fibroma cannot be expected in these affections; hence the hypertrophy may, as it does indeed, involve more markedly different strata of the papillary structure under differing conditions.

In construction the papillary type is nearly always readily recognisable, in spite of the excess of dense cuticle overlying the papillæ. The microscopic characters are also, as a rule, very distinctive and well-marked at the free surface; whilst at the base, in some of the larger chronic growths, an amount of connective tissue embracing closely packed cells generally exists.

Whilst quite benign as a general rule, it is well to remember that apparently simple warts, especially on the scrotum, face, and hands, may, as the result of long-continued irritation, become cancerous.

Symptoms and Diagnosis.—The warty character and raised surface distinguish papillomatous growths of the skin from any form of tumour or ulcer; and although on any mucous surface where they are found—rectum, bladder, or larynx—their external characters vary, yet the peculiar outstanding fringe-like surface exists in all. *See VILLOUS TUMOURS.*

Treatment.—Putting aside the conditions which have a venereal origin, to be treated as part of a general complaint, all plans for curing papillomatous affections should proceed, in the first place, on the principle of removing the cause when such exists. If the affection does not disappear upon the cessation of the cause, it must be dealt with radically, either by caustics, escharotics, or ligature, if small and localised; larger growths, and especially any whose bases are indurated, should be somewhat widely removed by the knife, scissors, or even *écraseur*. ALFRED WILLETT.

PAQUELIN'S CAUTERY. *See CAUTERY.*

PARACENTESIS. — Paracentesis means literally a pricking through, and the term is employed to signify the tapping of a cavity by means of a puncture, as opposed to the evacuation of its contents by means of an incision. It is generally confined to tapping the abdomen, the pleura, the pericardium, or the ventricles of the brain.

Paracentesis may be performed either with the aspirator or with a trocar and canula, the latter being often specially adapted for the cavity which it is required to puncture. The method of using the aspirator will be found under *ASPIRATION*; with regard to the use of the trocar, a

few general points may here be stated. First, it is sometimes thought advisable to make a minute preliminary puncture through the skin with a scalpel, in order to facilitate the introduction of the trocar; but, if the instrument be sharp, and if the canula do not project beyond the neck of the trocar, this precaution, which involves increased pain to the patient, is, in most cases, wholly unnecessary. Secondly, it is of importance, during the process of tapping, to guard against the entrance of air, which, in the case of any of the cavities under consideration, may happen from powerful respiratory movements on the part of the patient. This accident may be guarded against, in some cases, by keeping up firm pressure upon the surface of the part which is to be emptied; but it may be more securely attained, in the case of the chest or abdomen, by employing a canula to which an india-rubber tube is attached, the other end passing beneath the surface of some antiseptic fluid, contained in a vessel placed below the level of the patient's body.

A convenient arrangement is that in which the trocar forms the end of a piston hermetically fitting into the canula, which is prevented by a stop at the outer end of the latter from being completely withdrawn; the part to which the caoutchouc tube is fixed leaving the canula at some point in its side. The trocar, on being withdrawn to the utmost possible extent, does not allow the entrance of air into the canula, and the fluid flows out through the lateral opening. This instrument presents the disadvantage of being rather difficult to clean, which leads to the observation that it is a matter of the greatest importance that, whatever instrument be used, every part of it should have previously been thoroughly washed with a strong antiseptic material (carbolic acid lotion, 1 to 20, is the best). For it may easily happen that an instrument, which in the ordinary acceptation of the term is clean, may introduce the causes of putrefaction into the cavity operated upon, and may change a simple and aseptic serous effusion into a collection of stinking pus, thus endangering the health, or even the life, of the patient. Thirdly, it is well to draw the skin slightly to one side before making the puncture, so that the track made by the instrument may ultimately be valvular, and the leakage of fluid after its withdrawal may thus be prevented. Fourthly, the slight pain of the puncture may, if it is thought advisable, be prevented by freezing the skin of the part either by the application of ice and salt, or with the ether spray.

PARACENTESIS THORACIS.—The description of paracentesis thoracis will be found in great measure in the article EMPYEMA. Paracentesis, as opposed to free incision, is, however, seldom to be recommended for the evacuation of pus from the thoracic cavity, and in its application is chiefly confined to cases of serous effusion. If the aspirator be employed, it is well to use one in which a gradual exhaustion can be practised (the bottle aspirator), as opposed to the original instrument of Dieulafoy; it being unadvisable to run the risk of producing, by sudden exhaustion, the rupture of some small vessel in the lung, and so giving rise to a hæmothorax. For the same reason, it is best to employ a canula and trocar and not a perforated needle, so that, on withdrawing the trocar, the lung is free from the risk of being wounded. By a suitable arrangement of stopcocks (namely, by interposing a three-way tube into that leading from the canula to the bottle), it is easy to convert the aspirator into a syphon, and so empty the chest without risk of producing undue negative pressure. It should be remembered that, in performing paracentesis thoracis, it is not intended to empty the chest. In the first place, it is generally impossible to do so; in the second, it is not necessary, because the removal of part, sometimes even of a comparatively small quantity of a serous effusion, is usually followed by the complete absorption of the rest; and thirdly, the removal of a very large quantity may occasionally lead to dangerous collapse.

The rule is to continue the evacuation, if the patient's pulse and general condition remain good, so long as it takes place readily, producing no cough; but to stop at once if there be any cough or the slightest appearance of blood in the fluid drawn off. The aspirator in most cases answers the purpose extremely well; but if it be decided to employ a trocar and canula, either because the fluid contains flakes of lymph which do not readily flow through a fine tube, or for any other reason, such an instrument as that mentioned above may be used; or one which is flattened may be found more convenient, if the ribs be naturally close together, or if they have been approximated by contraction of the chest. It is not only important to see that the canula fits close round the neck of the trocar, but also to take the precaution of plunging it with one thrust through the thoracic parietes, regulating the distance to which it is made to enter the chest by placing the index finger at a suitable spot on the side of the canula.

In this way, the accident of separating the pleura from the ribs and pushing it before the trocar—a not uncommon one—is effectually avoided. If neither of the instruments described be at hand, an efficient arrangement for preventing the entrance of air into the chest may be made by attaching a piece of muslin, folded as when used for a petticoat-tube, to the end of the canula. During the puncture it is held round the trocar, and afterwards, whilst fluid escapes readily from it, it is impossible for air to find its way back through it.

It may be mentioned here that Mr. R. W. Parker, with a view of more completely removing the fluid than is otherwise possible, has suggested and put in practice the plan of puncturing the chest at another point with a fine needle, which communicates, by means of an india-rubber tube, with a bottle containing cotton-wool or some other means of purifying the air that passes through it. In this way purified air enters the chest as the fluid escapes, and the hydrothorax is converted into a pneumothorax, the air being, as was hoped, subsequently absorbed. Sufficient experience has not yet been obtained to warrant the recommendation of this procedure.

The spot to select for puncturing the chest is a matter of small consequence, only it is advisable not to go too low, for fear of injuring the diaphragm. About the sixth or seventh space, just in front of the posterior fold of the axilla, is usually found the most suitable position.

PARACENTESIS ABDOMINIS may be performed with the aspirator or the trocar; or another method may be employed, which was suggested by Dr. Reginald Southey—viz. the introduction of several minute perforated needles, through which the fluid escapes *guttatim*. These are left *in situ* for a considerable time, and it is maintained that the effusion can, by this plan, be removed with less chance of collapse than is involved in the more rapid processes, and without entailing any risk of consequent peritonitis.

If either of the other plans be adopted, a few precautions are necessary. First, it should be ascertained that the bladder is empty, so that the instrument may not pass into this viscus instead of into the peritoneal cavity; secondly, it must be demonstrated that there is dulness at the point selected, so that it may be certain that no coil of intestine is punctured, as may happen, even though the peritoneal cavity be full of fluid, if the bowel be bound to the abdominal wall by adhesions; thirdly, a wide, many-tailed

bandage should be made to encircle the abdomen, the ends of which should be firmly tightened by assistants standing upon each side of the patient, a hole having been previously cut in it opposite the point to be punctured. In this way the flow of the fluid is encouraged if the simple trocar be used, and the tendency to collapse of the patient, from the sudden diminution of pressure, is prevented. After the completion of the operation the bandage is not removed, but its ends are firmly secured on the front of the abdomen, after previously carefully sealing the puncture with collodion to prevent the possibility of leakage, such leakage being not unlikely to lead to peritonitis.

The spot usually chosen for puncture is in the middle line, midway between the umbilicus and the pubes, though circumstances may arise in which other situations are more advisable.

PARACENTESIS CAPITIS is performed for chronic hydrocephalus; it is not an operation from which, to judge by experience, much, if any, advantage is to be gained, the fluid almost always, if not invariably, collecting again with more or less rapidity. It is, however, a proceeding which, if carefully performed, appears to involve little or no risk to the patient. The fluid is usually in the distended cerebral ventricles; but the distension is so great that the brain substance covering it is much thinned, and it is therefore found at a very short distance from the surface. A fine exploring trocar is the right instrument to employ, and an ounce or two of fluid should, as a rule, be the limit of the amount withdrawn. The writer has, however, in one case adopted the plan of purposely leaving the puncture unsealed, so that the fluid might drain away after the manner of paracentesis abdominis by Southey's tubes; but, although no mischief in this case resulted, he is not disposed to recommend the plan to others, for on carrying out the principle a step further, and introducing a single horsehair into the puncture, a sharp attack of meningitis was the result. It would obviously be unwise, in dealing with such a delicate organ as the brain, to withdraw a large amount of fluid suddenly, and, *a fortiori*, to employ the aspirator for the purpose. The surgeon may select any point, away from the position of one of the sinuses, where the bony part of the skull is absent. Such spots are usually plentiful in cases of chronic hydrocephalus in young children, and a convenient place will be found, at a short distance from the middle line, in one of the usually widely gaping

limbs of the coronal suture. It is needless to say that in older children, where the skull is completely ossified, the operation is neither called for nor admissible.

PARACENTESIS PERICARDII is an operation which has suggested itself to many surgeons and physicians, but has not till comparatively recently been much used. Trousseau was in favour of employing the bistoury for the operation, but it can hardly be doubted that it is more safely performed with a fine exploring trocar or the aspirator; for it must be remembered that, although the pericardium is for a considerable extent uncovered by lung, the pleura on the left side reaches almost, if not quite, as near to the middle line as on the right side. Thus, unless the instrument is passed quite close to the sternum in the fourth or fifth interspaces, it must almost necessarily pass through the pleura, if this be not already obliterated by adhesions; and, although the passage of the aspirator needle will be probably productive of no evil consequences, the admission of air into the pleura, which will almost necessarily follow the use of the bistoury, would be an unfortunate and serious complication. The instrument is to be passed then close to the sternum in one of these spaces, or at such a distance from it as to avoid the internal mammary artery, which is coursing downwards behind the costal cartilages, and it should be directed obliquely upwards and outwards so as to avoid puncturing the heart. Dr. S. West strongly recommends the fourth interspace, at one inch from the end of the sternum, but the third, the sixth, the seventh, and the eighth have been selected, and in three cases at least the pericardium has been reached on the right of the sternum. It may be mentioned that simple puncture of the heart with a needle is not likely to be followed by any serious consequences, as is shown by the fact that it has been occasionally done accidentally, and sometimes purposely, for the sake of producing contraction of the ventricle in apparent death from chloroform. In Dr. Samuel West's case, and in some others, a drainage-tube was inserted into the pericardium, and the patients recovered; in one case the opening was made through the pleura, which had previously been incised for the evacuation of an empyema. RICKMAN J. GODLEE.

PARAMETRITIS. See PELVIC CELLULITIS.

PARAPHIMOSIS is the retraction of the prepuce behind the glans penis, where it becomes fixed owing to the constriction

of the preputial orifice. In childhood, the deformity is caused by the retraction of a long foreskin with a contracted orifice. In adults, this may also be the cause, and paraphimosis is not infrequently brought about during coitus. It may also arise as the result of venereal infection. The extension of a balanitis to the preputial mucous membrane having inflamed and thickened the prepuce, a successful attempt is made to retract it behind the glans, when it is found impossible at the moment to replace it. It is obvious that the tight, constricting band of the preputial orifice behind the glans, is the immediate cause of the return of blood from the part being prevented. Oedematous swelling soon comes on, and in cases where relief has not been soon afforded, ulceration or even sloughing of the glans has been known to take place. It is of importance to recognise the exact spot at which the constriction is situated. Immediately behind the glans is a furrow, deeper on the dorsal aspect. In paraphimosis there will be noticed behind this furrow a fold of swollen mucous membrane, and then another and deeper sulcus. This second sulcus represents the mucous membrane of the preputial orifice, and is the site of the constriction.

The *treatment* should be directed to secure immediate reduction. In ordinary cases this may be effected as follows: oil the glans penis well, then lock the fore-fingers of both hands above and behind the glans, and the middle fingers below. With both thumbs make steady pressure on the glans, at the same time endeavouring to slip the prepuce forward by traction with the fingers. The operation is a painful one, and in children it may be needful to administer an anæsthetic. Should this manipulation fail, an attempt should be made to reduce the swelling by the application of an elastic band wound firmly round the glans. On this being rapidly unwound, it may be possible to slip the prepuce over the diminished glans.

When, however, it is found impossible by these means to reduce a paraphimosis, recourse must be had to incision. Remembering the description given above as to the point of constriction, a vertical incision half an inch long should be made at that spot with a curved, sharp-pointed bistoury. The constriction immediately yields, sometimes with a snap, and reduction is effected with ease. The after-treatment consists of injections of carbolic or boracic acid lotions, and warm fomentations if pain and swelling should continue.

PAUL SWAIN.

PARONYCHIA. *See* WHITLOW.

PAROTID TUMOUR.—The tumours growing in the substance, or upon the surface, of the parotid gland, most commonly met with, and to which the name of 'parotid tumour' is usually applied, are of a cartilaginous nature. But, mixed with the cartilage is usually a variable amount of soft embryonic connective tissue (myxoma), together with fibres enclosing spaces wherein are contained cells resembling those proper to a lymphatic gland.

These tumours are irregularly lobulated in shape and of firm consistence, giving a sense of elasticity to the touch, with here and there softer portions. They are enveloped in a dense capsule, and usually embedded in, and closely adherent to, the substance of the parotid gland. Sometimes they are freely movable upon the parts beneath, but more often they are covered by the fascia of the parotid, and have made their way between the lobes of the gland, which may be partially absorbed by their pressure. Thus, while the greater part of the tumour may project beneath the skin, in front of or behind the lobe of the ear, there may also be processes extending deeply behind the ramus of the jaw, even down to the styloid process and carotid sheath; and the facial nerve or some of its branches, and the external carotid artery and jugular vein are often adherent to or surrounded by some part of the growth.

These tumours increase slowly, and do not often attain a very large size; they are non-malignant, and are troublesome chiefly because of the deformity they produce, and the pressure upon and displacement of adjacent structures.

Occasionally, however, parotid tumours are met with which recur after removal, or even exhibit malignant characters; these are usually softer, of more rapid growth, and with a tendency to early adhesion to the skin.

The only *treatment* applicable to a parotid tumour is removal; and this should be done early, so as to avoid, as far as possible, the dangers incident to its extension among the deeper tissues of the part. A free incision should be made over the posterior border of the tumour, and this may be joined, if needful, by another passing forwards at a right angle to the first. The capsule of the tumour should be opened to a corresponding extent, and the dissection kept as much as possible within it, for the capsule generally separates the tumour from the important adjacent struc-

tures. When, however, the tumour extends deeply, the dissection will always be difficult and require much caution, especially in following the processes of the growth which extend behind the jaw and in the direction of the styloid process.

The facial nerve or its branches may, however, be so intimately connected with the tumour that it will be impossible to avoid its division. But the resulting facial paralysis is not necessarily permanent. If the ends of the nerve can be found, they should be brought together by a fine catgut suture, and the function of the nerve may be re-established. If, however, any considerable portion of the nerve is removed, or if there be much suppuration in the wound, the paralysis will persist. Every care should, therefore, be taken to secure immediate union of the wound, the edges of which should be carefully adjusted with fine sutures, for the vascularity of the tissues of the face and neck favours the rapid healing of even extensive wounds.

J. WARRINGTON HAWARD.

PATELLA, Dislocations of the. There are five dislocations of this bone: viz. *outwards, inwards, upwards, by semi-rotation* (edgeways), and *by complete version*.

DISLOCATION OUTWARDS is the most common, and it may be *incomplete* or *complete*. When incomplete, the inner articular facet rests upon the cartilage of the external condyle, and the outer edge projects. When complete, the bone lies to the outer side of the anterior prominence of the external condyle. It is especially frequent in knock-kneed persons, which is to be explained as follows: Owing to the oblique direction of the rectus muscle from origin to insertion, during contraction it tends to displace the patella outwards, a tendency which, under normal conditions, is counteracted by the anterior prominence of the external condyle. With genu valgum the obliquity of the muscle is increased, and the prominence of the condyle no longer suffices, under these conditions, to prevent the patella from being displaced outwards. Occasionally it is produced by violence, or it may be *congenital*, and then is often associated with talipes or other deformity. A slight twist inwards whilst dancing, in a person of lax fibre with knock-knee, is often sufficient to cause this dislocation. It is, usually, easily reduced by pressure when the limb is raised. In cases of difficulty, violent flexion has sometimes been found to succeed after other means

have failed. The joint should afterwards be kept at rest till the synovitis has subsided, and a knee-cap, with a spring to support the patella in position, should be worn when the patient commences to walk.

DISLOCATION INWARDS is much less frequent than dislocation outwards, and is more often due to direct injury. It may, however, be caused by muscular action, especially where there is a tendency to genu varum. It may be *complete* or *incomplete*. In the latter case the inner edge projects, and the outer articular facet is applied to the inner condyle. Reduction is, usually, easily effected in a manner similar to that recommended for dislocation outwards, and as a rule little ill-result follows; but in one case, recorded by Key, suppuration and death resulted, though there was no external wound.

DISLOCATION UPWARDS occasionally occurs as the result of a sudden powerful contraction of the quadriceps extensor muscle, whereby the ligamentum patellæ becomes ruptured. In more than one case to which the writer has been called, under the belief that this accident had occurred, he was able to distinguish the extreme tip of the patella attached to the upper end of the ligament, and the case was, therefore, really a fracture. The treatment should be precisely the same as for fracture of the patella, that bone being held down by some mechanical contrivance until firm union of the ligament has taken place.

DISLOCATION BY SEMI-ROTATION.—In this very rare but interesting dislocation, the patella becomes rotated on its vertical axis, and so fixed between the condyles that its surfaces are directed laterally and its edges antero-posteriorly. It would appear to be brought about by a stage in rotation beyond that which prevails in the case of incomplete lateral dislocations; and either edge may be directed backwards and fixed between the condyles. The inner edge is more frequently posterior, and this is what one would anticipate from the greater frequency of the dislocation outwards. It has occurred in children of thirteen and fifteen, as the result of muscular action, but more often results from direct injury, and this has happened on several occasions during horse exercise. The leg is usually extended or slightly flexed, and the edge of the patella makes an unmistakable prominence in front of the joint. Reduction has, sometimes, been effected without difficulty by pressure and extension; in other cases, this method has completely failed, and the bone has been replaced by forcible

flexion. The extreme difficulty occasionally experienced, even after division of the extensor tendon and ligamentum patellæ, points to some other cause than muscular action as producing the fixation; but these cases appear to have been before the days of chloroform. Should all other means fail when the patient is under an anæsthetic, the writer would not hesitate, under proper antiseptic precautions, to make a small incision into the joint on the side of the patella, and there introduce a metal lever to raise the bone into position. His experience of antiseptic incision of the knee-joint, for the removal of loose cartilages and for knock-knee, quite justifies him in recommending this method under the restrictions stated; but without such care it would be hazardous, in illustration of which Wolff's case may be mentioned. This surgeon made a long open wound in front of the joint, in order to divide the extensor tendon and the ligamentum patellæ. He failed to replace the bone, and the patient died from suppurative of the joint.

DISLOCATION BY COMPLETE VERSION.—As dislocation by semi-rotation is one stage further than incomplete lateral dislocation, so complete version is a further twist on the vertical axis beyond semi-rotation. The articular facets of the patella are directed forwards, and its anterior surface faces the condyles of the femur, whilst the tendon above and the ligament below are twisted, and stand out as cords beneath the skin. Castara has related a case which occurred in a girl of seventeen, the patella being twisted from within outwards; and Sue has mentioned a case in which the rotation was from without inwards. Castara readily reduced his case by simply twisting it round with his finger and thumb. In cases of difficulty, the methods already described for dislocation by semi-rotation may be tried.

R. CLEMENT LUCAS.

PATELLA, Fracture of the.—This bone is most commonly fractured in males between the ages of twenty and fifty, though cases are occasionally met with in the young, and in persons advanced in life. It is much more common in men than in women.

Causes.—Though sometimes the result of direct violence, as of a fall on the knee, a kick, or a blow, it is most frequently produced by muscular action. When the knee is flexed to an angle of about 110° , the patella is mounted on the most prominent part of the condyles of the femur, in a position which, while it greatly increases the leverage of the quadriceps,

leads to so severe a strain when this powerful group of muscles suddenly contracts, that the bone frequently snaps across, a little below the middle. The fall which many believe has caused the fracture is, in fact, merely its result. Observant persons, indeed, have often reported that during a violent muscular effort they both heard and felt the bone snap, and that then, losing all power in the limb, they fell to the ground. Transverse fracture may occur at any level, sometimes so near the ligamentum patellæ that the lower fragment is so small that it can scarcely be felt; sometimes near the upper limit of the bone. Occasionally, the quadriceps extensor not only produces a transverse fracture, but those of its fibres which are attached to the sides of the bone lead to vertical fracture and wide lateral separation of the fragments. When the result of direct violence, the fracture may be vertical, oblique, or comminuted and stellate. Morris mentions a case of incomplete fracture involving only the articular aspect of the bone. Compound fracture is rare, and is probably always due to direct violence.

In the great majority of cases, fracture of the patella extends into the joint, though, when it is seated at the lower non-articular portion of the bone, the soft parts may shut it off from the synovial cavity. The amount of separation of the fragments depends on the degree to which the aponeurotic structures at the sides of the patella are torn. When these escape injury separation is slight, but when, as is often the case, they are extensively lacerated, and when effusion occurs into the joint, the gap between the fragments becomes proportionately great. Immediately after the injury the knee-joint frequently becomes distended with serum and blood, and considerable extravasation may occur into the soft parts about the front and sides of the knee. Synovitis following the accident may add to the swelling of the joint. Suppuration very rarely takes place. Necrosis following fracture of the patella is a very rare event, though a few examples of it have been recorded.

Symptoms.—In the majority of cases the local symptoms are plainly marked, but occasionally they are so obscure that the injury may be easily overlooked. In transverse fracture, the fragments are generally separated by a distinct interval, which is increased on slight flexion of the limb, a movement, however, which should be used only in doubtful cases, and then with the greatest gentleness. When pressed from side to side in opposite directions, the frag-

ments can be felt to move on each other, or when one is tilted by pressure on its lateral border, the other is found to remain at rest. In transverse fracture with little separation, or in vertical or stellate fracture, the fragments may be moved on each other and crepitus be sometimes obtained. On tracing its borders, irregularity in the outline of the bone may be detected. Though the patient usually loses all power in the limb at the moment of the accident, and finds that any attempt at movement causes severe pain, it must not be forgotten that many cases are on record in which persons, with recent fracture of the patella, have been able not only to extend the leg but to walk for some distance, and even to walk upstairs upon the limb. Care must be taken not to mistake for the evidences of fracture either (a) the ridges and irregularities that are sometimes to be felt in a thickened bursa patellæ resulting from repeated attacks of inflammation; or (b) the hard edges of an effusion of blood following a blow and soon becoming firmly coagulated in the meshes of the periosteum; or (c) the sensation of crepitation which may be produced by the presence of recent blood-clot in the bursa; or (d) the altered shape of the bone resulting from osteo-arthritis. In some instances, fracture of the patella has been mistaken for mere traumatic synovitis, and has been detected only when effusion into the joint has been absorbed.

Transverse fracture of the patella is rarely united by bone. The possibility of this form of repair, however, is proved by many museum specimens in which a section across the line of fracture has been made. Generally, when separation is only moderate, the fragments are connected by a thick and broad ligament which occupies the interval between them. When the ends are wide apart, a band may extend between them consisting either of newly organised material more or less substantial, or of part of the thickened capsule, blended perhaps with the walls of the bursa patellæ. In many instances the fracture remains ununited, and the joint is closed in front only by the integuments. Although, when the patient leaves the surgeon's hands, the fragments are close together or are separated only by a slight interval, the uniting band may, with subsequent use of the limb, gradually stretch, so that a gap of from an inch to four or even six inches is formed.

A patient, who has once sustained fracture of the patella, is very liable to a repetition of the accident in the same or the opposite limb. In re-fracture, the bone

generally gives way above or below the uniting ligament, but in some cases the ligament itself is torn. Instances are on record, in which the same patella has been broken at as many as four different levels. Occasionally, both patellæ are broken at the same time. In some cases repair leaves the knee-joint stiff, and the patella fixed by fibrous adhesions to the condyles; no attempt, however, involving any force, should be made to restore movement by flexion, lest in doing so the union of the patella should be weakened.

Treatment.—The objects to be aimed at are the approximation and retention of the fragments in position, and a quiescent condition of the extensor muscles. When the joint is distended with effused blood and serum, or when acute synovitis has come on, no retentive apparatus can at first be used. The knee should be fully extended, and the limb raised to an angle of about 140° with the trunk. The joint should be covered with an ice-bag, or with evaporating lotion. In order to reduce swelling, some advise that the joint should be aspirated. This, however, although it has often been safely done, and although its effect is to allow the fragments to fall towards each other, is a proceeding which certainly is not essential, for the generality of cases do well without it; nor can it be regarded as free from the chance of an occasional serious mishap. It should, therefore, at least be reserved for cases in which the separation of the fragments is very considerable.

As soon as the joint will safely bear it, means should be taken to bring the fragments together. Owing to the prolongation of some of the fibres of the quadriceps tendon downwards over the superficial aspect of the patella, the upper fragment is prone to be tilted so that its broken surface, instead of presenting directly towards the lower fragment, looks upwards and forwards, and so that the interval between the ends is V-shaped, with its base outwards. Hence, although the fragments may be in firm contact on their deep aspect, they still show a gap in front, which it is often difficult or impossible entirely to remove. But this is not very material, for experience abundantly shows that, while bony union is very rare even when the fragments seem closely in contact, in the great majority of instances in which the ends are separated only by a moderate interval (less than three-quarters of an inch—and the space can usually be reduced to these limits), such firm ligamentous union will occur that the patient re-

tains almost perfect use of the limb. This ligament, indeed, is so strong that, in any subsequent injury, not it but the bone itself at some other level usually gives way.

In Steavenson's method, which is often successful, the limb is placed in a back splint, and the fragments are drawn together by two elastic bands, one of which passes from a hook at the inner side of the back splint below the knee, upwards over the superior fragment, and then returns to a hook on the outer side of the splint below the knee, while the other band passes in an opposite direction, is similarly fixed, and acts on the lower fragment. Another plan is the following:—A broad piece of stout moleskin strapping is cut, at one border, into the shape of a horse-shoe, with the ends prolonged. This is applied to the thigh so that its concavity surrounds the upper fragment, and is fixed by a bandage. The limb is now placed on a well-padded McIntyre or wooden back-splint, with a footpiece. The lower fragment is next fixed by a pad of lint, and with strapping passed around the limb and splint together. A bandage is then carried upwards over the limb and splint from the foot to the level of the lower fragment, and another is applied in a similar way to the thigh. To the two ends of the moleskin pieces of webbing are now sewn, and these are connected with india-rubber accumulators, which in their turn are fastened to a loop of webbing passed round the footpiece of the splint. By tightening this loop the upper fragment can be drawn down. It is best to introduce a pad beneath the concave edge of the moleskin, so as to avoid ulceration of the skin.

Malgaigne's hooks enable us to act directly upon the fragments, drawing them more closely together than any other method, and some surgeons still employ them. Their use, however, has been followed by diffuse inflammation round the patella and even by suppuration of the knee-joint, ending in some cases fatally, in others in ankylosis. Nor do they by any means ensure bony union. Hence, they have never come into general favour, and cannot be here recommended. In a serviceable modification of Malgaigne's plan two thick pieces of moleskin plaster cut out at their margins to fit the patella are applied, the one above and the other below the fragments, and the hooks are fastened into and made to draw upon these instead of being fixed into the patella itself.

The operation of opening and wiring the fragments together, first practised up-

wards of five-and-twenty years ago, has lately been advocated and practised by Sir J. Lister and others. In speaking of this proceeding, a line must be drawn between recent and old cases. (a) In recent cases the fragments are no doubt generally brought easily together, and, as a rule, the operation is attended with no serious complication; while in many instances, so far as examination shows, bony union is obtained. It may also be allowed that in a successful case much time is saved. The objections, however, to the operation are: (1) that a very satisfactory result is generally to be obtained without it, so good indeed that the patient is conscious of no impairment of the limb; (2) that bony union after it can by no means be guaranteed; (3) that it entails, as some cases have already only too plainly demonstrated, the risk of suppuration of the joint and other very serious complications. These objections are, in the eyes of the great majority of surgeons, fatal to the adoption of this method. (b) In cases of old fracture, with retraction of the fragments, it has been found difficult or impossible to bring them into contact, in consequence of the shortened condition of the quadriceps extensor. In some instances, even though the extensor has been completely divided, the fragments could not be brought together; in other cases, though adjustment was accomplished, no bony union occurred. In short, the prevailing opinion in regard to this operation is that in cases of recent fracture it is uncalled for; while in many cases of old fracture it is often impossible to carry it out in a satisfactory manner.

Refracture must be treated in the same manner as the primary injury. Unfavourable as the prognosis appears at first sight, the result is often very satisfactory, and it is surprising to see how fully the power of the limb is retained, even when the patella has become by repeated fractures divided into three or four fragments, united by intervening ligamentous bands. A source of weakness, after fracture of the patella, lies in the great atrophy which occurs in the quadriceps muscle. Something may be done to reduce the amount of wasting by hot douching and shampooing, and the use every morning and evening of a mild continuous electric current (six or eight cells).

Much difference of opinion exists as to the time during which, after fracture of the patella, some apparatus should be worn to prevent flexion of the joint. This period, however, must doubtless vary with the case.

When not only the patella has been broken, but the fibrous structures at its sides have been widely torn across, so that considerable separation has occurred and the uniting ligament is weak and apt to stretch, the knee ought to be kept in a straight position for six months; while in instances in which separation has been slight, and a strong and short ligamentous band has formed between the fragments, some flexion of the limb may be allowed after three months. Each case, however, must be watched to see whether the band is yielding and the gap between the fragments increasing, it being remembered that, in many instances in which union was close when the patient was dismissed, a gap of from four to six inches has gradually formed. Much, too, will depend on the patient's calling. If this involves the carrying of heavy loads, or is otherwise physically laborious, the extended position must be maintained much longer than would otherwise be necessary. A convenient apparatus for maintaining extension consists of a pair of antero-posterior leather splints, accurately moulded to the lower half of the thigh and upper half of the leg, and strengthened by light steel supports. The splints may be prevented from slipping by two narrow steel prolongations, fitting into tubular sockets in the sides of the heel of the boot. An excellent appliance, long used at the Middlesex Hospital, consists of a strong-laced leather knee-cap made in two pieces, one extending eight inches or more up the thigh, the other six inches or more down the leg, and connected with each other by steel rods on the outer and inner sides. These rods are jointed opposite the knee, the joint being so constructed that the amount of flexion which it allows, and which is at first very limited, can be gradually increased.

In cases of vertical or oblique fracture of the patella, the limb must be raised in the extended position, and the fragments readjusted and maintained in place by pads and circular turns of a bandage. In many cases, however, of these fractures, separation is so slight that all that is necessary is to keep the limb at rest in the position just mentioned, and supported on a back-splint for four or five weeks, when the patient may be allowed to resume exercise gradually, the knee being at first guarded by a light back-splint, to prevent flexion.

HOWARD MARSH.

PEDICULI.—The presence of pediculi, or lice, upon different parts of the body, gives rise to a disease called phthiriasis,

which differs somewhat according to the locality. It is in reality a form of eczema dependent on the local irritation of the pediculi, and it differs according to the habits and situation of the pediculi which give rise to it. There are three kinds of lice which generally attack the body: *pediculi capitis*, *corporis*, *pubis*. The symptoms, which vary in the case of each of them, together with the diagnosis and treatment, which depend on a knowledge of their habits, must be considered separately.

PEDICULI CAPITIS.—*Symptoms.*—As a rule, the patient complains of soreness and great irritability of the head; or the glands in the occipital region especially, and also those in front of the ear and at the side of the neck are swollen and even suppurate, giving rise, at first sight, to the notion that the patient is strumous. But the hair is matted together, especially at the roots, with thick crusts and scabs, and a very slight examination will reveal the presence of eczematous patches and small erosions on the scalp. Sometimes, especially in women with long hair, the erosions are deep and inflamed, and the skin is pigmented under the long hair in the neck. If this be lifted up, the pediculi will soon proclaim their presence by their active movements.

Diagnosis.—An examination of the individual hairs will complete the diagnosis, if anything further be required. Fastened to them, usually close to their roots, will be found the nits or eggs (small grey masses about the size of a small pin's head). One only, as a rule, is found on each hair; if more than one is present, those nearest the root are the newest, and if the nits are situated more than an inch from the head, it is quite certain that the disease has existed for some time, as the hairs have had time to grow considerably since the nits were deposited upon them. It is important to observe the exact way in which the nits are attached to the hairs, for without such knowledge they cannot be thoroughly removed. Around the hair will be found an elongated ring, which is cemented to the hair, and to the outside of which the nit is attached. For this examination a small magnifying glass should be employed. The pediculi themselves are small grey insects, having their habitat near the hair-roots, where they are warmest and safest. They are about $\frac{1}{10}$ of an inch in length, and capable of very active movements. They escape from the nits about nine days after these have been deposited. Nine days later they are full-grown, and in about nine more are capable of reproduction.

Treatment.—From the above description it is obvious that the treatment must be directed, not only towards killing the lice, but likewise to the destruction of the nits. The simplest plan, by far, of effecting this object is to shave the head, which plan leaves nothing but the eczema to treat. This is readily cured by any simple emollient, such as vaseline, zinc ointment, or one part of liq. plumbi subacet. and two parts of olive oil. If, for any reason, it is desirable to retain the hair, one of the following methods will be found to succeed admirably: a linseed-meal poultice mixed with carbolic acid (1 in 40 parts of water) readily kills the lice, without running the risk of letting any of them escape. The same end can be effected by washing the hair with plenty of soap and carbolic acid (1 in 40), or by applying equal parts of petroleum and olive oil, with enough Peruvian balsam to mask the smell. To get rid of the nits which still remain behind, daily washing is necessary, together with the use of a fine-toothed comb after the roots of the hair have been moistened with a little vinegar. The effect of this application is to loosen the little rings before described, by which the nits are attached to the hairs, and they can then be gradually drawn off the hairs by the aid of a fine comb, just as a ring is withdrawn from one's finger. This process should be carried on for at least a fortnight after the last louse has disappeared, after which time there is no fear of any more eggs being hatched.

PEDICULI CORPORIS.—*Symptoms.*—The chief symptom of this disease, as of the first, is, essentially, intense itching, but it is limited to the body, as these lice do not invade the head. The skin is marked by long scratches, caused by the nails of the patient, by wheals, papules, and even sores. In the worst cases the whole skin is dark and pigmented, from the extravasated blood which has become altered in the subcutaneous tissue, and the course of the lymphatics is marked out by lymphangitis. It is scarcely possible, with care, to mistake the disease for anything else; it has been, however, confounded from its colour with Addison's disease; from its wheals, with urticaria; and, from its scratches and ulcers, with impetiginous eczema.

Diagnosis.—To come to an absolutely certain conclusion, the clothes must be searched, as in them it is that the louse resides; the body is only his happy hunting-ground. Wherever there are folds in the clothes, e.g. just below the armpits, round the waist or the neck, the greatest traces

of his ravages will be seen, whilst in the axillæ and on the contiguous surfaces of the buttocks where the clothes never touch, no traces of the scratching are to be seen. It is essential that every article of clothing should be carefully examined, as, sometimes, an old flannel belt or truss may be the lurking place in the cleanest of individuals. The pediculus corporis or *P. vestimenti*, as it should be more properly called, differs from *P. capitis* in being larger and more active; the head is elongated and more oval, the antennæ larger, and the colour dirty white with blackish margins.

Treatment must be directed rather to the clothes than to the skin. If the clothes are boiled or baked, all the symptoms will speedily disappear. If these precautions be taken, it is not necessary to destroy the clothes. The treatment of the skin, if any be required beyond a warm bath, is the same as that prescribed in the case of *P. capitis*.

PEDICULI PUBIS.—*Symptoms.*—Itching, as in the preceding cases, is the most prominent symptom. It is more constant though not so violent as in *P. corporis*; and the scratches are more like those on a person affected with scabies.

The *diagnosis* is readily effected by searching for the louse, which is shorter and broader than *P. capitis*, has a fiddle-shaped head, and resembles a miniature tortoise. The two front pairs of legs are used for walking, whilst with the claspers on the hinder he sticks tight to the hairs. The nits are situated so near the base of the hairs that it is best to shave them to ensure a complete cure. The pediculus pubis will affect the whiskers, beard, moustache, eyelashes, and chest of hairy men, but never invades the clothes or even enters the head. It should be borne in mind that this affection, though usually caught during coitus, may be contracted in other ways.

The *treatment* which is commonly adopted is to rub in ung. hydrargyri, continuing the treatment as each fresh lot of nits is hatched. Occasionally, however, in delicate skins this produces a violent attack of eczema, rendered oftentimes all the more violent by the additional application of the ointment, under the impression that the extra irritation is caused by the pediculi and not by the ointment. No fear of such a disaster need be entertained if equal parts of ung. hydrarg. ammon. and lard are employed, or petroleum prepared as in the case of *P. capitis*. Much irritation may be avoided by sprinkling a little chloroform on the affected parts, and then washing off the

stupefied lice, after which the ointment, &c., may be trusted to prevent the nits from doing any further harm.

W. BRUCE CLARKE.

PELVIC ABSCESS.—Abscess may form in the pelvic cavity of a female subject as the result of several disorders, particulars of which are to be found in works upon obstetrics and diseases of women. Inflammation of the connective tissue of the pelvis, generally termed pelvic cellulitis or parametritis, is probably the most frequent cause of pelvic abscess. Pelvic peritonitis or perimetritis is a less frequent cause of the same complication.

Although specific discharges seldom, if ever, set up suppuration around the bladder and urethra in women, they may lead to pelvic cellulitis or peritonitis, and thus indirectly cause abscess. In such a case, the surgeon must lay more stress upon a history of child-bearing or abortion than on the recent or present existence of gonorrhœa in the same patient. For it is questionable whether gonorrhœa, in single women, is so frequent a primary cause of severe pelvic peritonitis as has been asserted; but it is a certainty that the same disease may set up pelvic peritonitis of the worst type if the patient be delivered, or have an abortion during its existence. Thus, in venereal out-patient practice in hospitals, a large proportion of sterile women with gonorrhœa may be watched for months, but pelvic peritonitis and pelvic cellulitis will not be found to be common among these cases. Let the surgeon turn to the gynecological department of the same hospital, and he will not fail to observe numerous cases of pelvic peritonitis and cellulitis, and not a few in the suppurative stage; nearly all the cases will be in married women who have had children or miscarried, and a history of gonorrhœal infection will, unfortunately, be found in a large proportion. Noegorath's theory of the frequent relation of gonorrhœa to sterility does not come within the scope of the present subject, but it should be noted that in many sterile cases there may have been an overlooked early abortion.

Carelessness in the use of the sound, and cutting operations about the cervix uteri, may be the cause of suppurative pelvic cellulitis or peritonitis. Here, again, the presence of gonorrhœa would greatly increase the dangers of these minor operations. The suppuration of a morbid but non-inflammatory deposit in the pelvic cavity is another cause of abscess. Under this

head must be included two very different conditions, pelvic hæmatocele and extra-uterine fetal cysts. The suppuration of a portion of ovarian cyst, adherent to the pelvic structures, is not infrequent, especially in the case of dermoid cysts. The abscesses set up by fetal and dermoid cysts often burst into adjacent cavities, especially the bladder and rectum, and seldom point above the groin.

Symptoms and Diagnosis.—The premonitory symptoms of suppuration are the same in the female pelvic structures as elsewhere. See ABSCESS. They are often masked or overlooked in this particular kind of abscess. Women may complain of feeling suddenly hot or suddenly cold when simple, non-suppurative, inflammation is spreading in the pelvic connective tissue or in the peritoneum, and sudden rises of temperature often occur under these circumstances. Nevertheless, rigors and rise of temperature will always give grave suspicion of abscess, when occurring in any of the diseases mentioned above as predisposing to suppuration. When these symptoms have occurred, the diagnosis of the abscess by touch is far from being easy. It is generally surrounded by a wall of indurated inflamed structures, so that until it has pointed and is about to burst, none of the characteristic fluctuation can be detected. Parametric abscess often forms in the hard irregular inflammatory deposit which rises out of the pelvis in bad cases of pelvic cellulitis. Dr. J. Matthews Duncan has shown how such abscesses may extend into the thigh, the iliac fossa, the psoas muscle, or even as high as the kidney. This must be taken into account when abscess is detected in those regions in any adult female, single or married; and the surgeon must not mistake persistent lumbar pain, due to the pelvic disease, for evidence of spinal caries. A tender fluctuating swelling presenting in Douglas's pouch or above Poupert's ligament, after general symptoms of suppuration, is, after all, the only trustworthy evidence of pelvic abscess.

The *diagnosis* of abscess from the two chief inflammatory pelvic diseases, in their earlier stages, can only be proximately effected by a very careful unravelling of the history of the individual case. In pelvic cellulitis or parametritis, abscess may form at any stage, sometimes very early, whilst, when once the disease in question has occurred, the patient may, many years after its onset, suffer from a 'residual abscess,' formed in or about the residues of former

inflammations. In pelvic peritonitis or perimetritis, abscess appears to present generally in Douglas's pouch. Fluctuation in that pouch, in cases of perimetritis, may indicate a collection, not of pus, but of serum ('serous perimetritis'). The sudden onset of pelvic hæmatocele distinguishes it from pelvic abscess, and the collection of effused blood tends to become harder and less painful, whilst the reverse will occur where abscess has formed. Nevertheless, diagnosis is often obscured in cases of suspected hæmatocele. The catamenial history must be taken into account when an extra-uterine foetal cyst is suspected; on the other hand, an abscess never begins with frequent attacks of metrorrhagia and crampy pains without fever. When a foetal cyst is diagnosed, and rigors set in, suspicion of its suppuration becomes very reasonable. When an ovarian tumour exists, it is often impossible to diagnose suppuration around, from suppuration within, its pelvic portion. Pelvic abscesses being fixed, may be thereby distinguished from distended Fallopian tubes and incipient ovarian tumours.

Prognosis.—The course of abscess, in cases of extra-uterine gestation and pelvic hæmatocele, is generally very irregular and uncertain; and it may be laid down as a rule, that pelvic abscess following pelvic cellulitis or pelvic peritonitis is a most troublesome disease, always tedious in its course, and never unattended by danger. The anatomical relations of the abscess prevent early or safe pointing, and, the abscess walls being rigid, especially in parametric cases, collapse is impossible, and fistulous tracks in the groin or genito-urinary passages may remain for years. The probability of a residual abscess, or of fresh acute attacks of suppurative inflammation behind the first abscess, is very strong. Rupture of the abscess into the peritoneal cavity is rare though not unknown. The abscess-cavity in an ordinary case, where the opening is external, may harbour septic material, with the usual disastrous results. Pelvic abscess most frequently opens in the groin, the rectum, or the vagina. This subject will be considered in connection with treatment. It frequently happens that, in the course of a pelvic abscess, there is a more or less temporary arrest of the formation of pus, whilst that already formed may partially dry up. It is clear that chronic abscess in this condition is a constant source of danger, when situated amongst the pelvic viscera, though far less serious in many other situations on the trunk or extremities. It may give rise to all the re-

sults which follow non-suppurative forms of pelvic inflammation. The inflammatory process may suddenly extend, fresh abscesses forming, or, still more frequently, fresh adhesions of viscera. We say fresh, since it is rare that any severe form of inflammatory disease of the pelvic peritoneum or cellular tissue is unattended, from the first, by such adhesions.

Abscess, from suppuration in or around an extra-uterine foetal cyst, places the patient in great danger from the risk of escape of pus into the peritoneum. It may burst into the vagina, and thus allow of the 'birth' of the relics of the foetus sometimes entire, more frequently piecemeal. The suppuration of the pelvic portion of an ovarian cyst is a subject that does not come entirely within the scope of this article. The suppurating cyst may rupture into the vagina or peritoneum, and always complicates the case most seriously.

Treatment.—Pelvic abscess is a disease which it is difficult to treat satisfactorily. The difficulty in ascertaining where the abscess will point, and the still greater difficulties due to the usual rigidity of the abscess-walls, are the chief sources of trouble in treatment. The commonest form of pelvic abscess is seen in cases of pelvic cellulitis after childbirth, and it generally bursts in the groin. When the complexity of the anatomical structures between the integument along Poupart's ligament and the pelvic connective tissue is remembered, it is not surprising that the pointing process is often tedious. The widespread induration, which can be felt over the region of the abscess, explains how impossible it must be for the abscess-wall to collapse with readiness. When symptoms occur indicating pelvic suppuration after childbirth, the surgeon must look out for any softening in the hard mass, which can generally be felt in one groin; but must not forget that the abscess may burst through the integuments over the iliac fossa, above the ilium, in the thigh, or near the anus. It has been known to find its way through the obturator or through the great sciatic foramen. Lastly, these 'parametric' abscesses may burst into the rectum or vagina. On the other hand, in pelvic peritonitis, from any cause whatever, abscesses tend to burst into the rectum or vagina: rarely into the general peritoneal cavity or the bladder.

Guided by these considerations, the surgeon must be watchful in cases of pelvic cellulitis, and test by gentle digital examination the relative softness of the

exudation in the direction of the groin and in the pelvic cavity. Bimanual palpation is sufficient for the purpose, and the uterine sound should be eschewed. When the abscess points in the groin it may be opened by a free incision, and the pus allowed to flow out. It is not advisable to press on the abscess from the vagina or from the abdominal walls, as there is an especial risk of admitting a quantity of air into the rigid-walled collection of pus. A drainage-tube is an absolute necessity, and the cavity should be frequently washed out with antiseptic solutions. Iodoform gauze pads make a good dressing. The process of closing is often much protracted.

When the abscess points into the rectum or vagina, the surgeon must not be eager to employ the aspirator. It is a dangerous instrument, though it still has the reputation of being safe for this purpose. Free incision and thorough drainage will be needed. It is impossible to employ full antiseptic precautions under these circumstances. Care must be taken that the tube be carefully fixed, and antiseptic solutions must be injected gently, lest some weak part of the abscess-wall be damaged; for abscesses in the direction of the rectum and vagina are often not so thick-walled as those pointing towards the groin. An iodoform bougie may advantageously be retained in the vagina during treatment, if the abscess have opened into that passage.

In cases of pelvic peritonitis the same treatment is needed; the abscess nearly always bursts into the rectum or vagina. When pelvic peritonitis occurs from no evident cause, such as childbirth, abortion—criminal or otherwise—or unsuccessful operations about the pelvic region, the surgeon must be prepared for surprises. On bursting of an abscess, foetal bones or masses of amorphous osseous tissue, hair, or sebaceous material, may escape with the pus. Independently of the general treatment of extra-uterine foetation and dermoid ovarian cysts, the surgeon's duty in such a case is to enlarge the opening very carefully and to extract the solid structures, which, after exposure of this kind, are more likely to set up complications than before. Antiseptic injections will then be very much needed. *See EXTRA-UTERINE FOETATION; OVIOTOMY.*

In conclusion, the surgeon, in treating any case of pelvic abscess, must never fail to remember that it represents other morbid conditions, which he must seriously take into account.

ALBAN DORAN.

PELVIC CELLULITIS.—This disease is termed 'parametritis' by several contemporary writers of high authority, chiefly from their objection to the word 'cellulitis' as unclassical. As the same writers, however, are those who rightly insist on the complete difference between this disease and 'perimetritis'—as they invariably term 'pelvic peritonitis'—it appears hardly advisable to employ terms so similar in sound, and therefore so liable to be confounded.

Pelvic cellulitis signifies inflammation of the cellular tissue of the female pelvis. Its pathology is that of cellulitis elsewhere, subject to local anatomical peculiarities. Hence, the surgeon must remember the relation of the fasciæ and peritoneum, and of the pelvic organs to the true cellular tissue of the pelvis. He should also bear in mind the anatomy of the lymphatic glands in the pelvis. The writer has repeatedly detected distinct enlargement of one of the obturator glands in the early stage of pelvic cellulitis. The enlarged gland may be felt by passing the finger up the lateral aspect of the vagina, then slipping it forwards along the tendinous origin of the levator ani muscle. When the anterior part of the attachment of that muscle is reached, the enlarged gland will be distinctly felt. A day or two later, should the disease have made progress, the gland will be embedded in inflammatory deposit, and its outline can no longer be defined.

Pelvic cellulitis is essentially a disease incidental to parturition. It is far less frequent in pregnancy, but is not rare under circumstances independent of the impregnated state. It generally arises in the cellular tissue around the cervix uteri. Pathologists often explain this fact by noting the abundance of this tissue in that region. The true reason is the frequency with which the cervix is exposed to injury involving its deep tissues, for such injury is probably the direct exciting cause of inflammation in the surrounding structure. Hence, damage to the cervix during parturition, the passage of a sound, or operative measures in its neighbourhood may all be causes of pelvic cellulitis. Septic material, entering a wound in the cervix, evidently produces similar effects to septic wounds in the neck or finger. The cervix is surrounded by a dense network of lymphatic vessels, as well as by cellular tissue. This explains the wide diffusion of the inflammatory process in the course of this disease. Cellulitis, beginning around the cervix, may certainly run its course without evidence of any complication involving the peritoneum.

When, however, it is set up in the very scanty cellular tissue between the body of the uterus and its peritoneal investment, it is hard to understand how the peritoneum can remain unaffected. Thus, it is frequently complicated with pelvic peritonitis, although that disease is probably caused, as a rule, by passage of septic material through the Fallopian tube into the peritoneal cavity. For the relation of gonorrhœa to pelvic inflammations, see PELVIC ABSCESS.

Symptoms.—Pelvic cellulitis almost invariably begins with those general symptoms observed in all other forms of cellulitis. Some women pay little heed to the early rigors and feverishness, which they attribute to sitting in a draught, or to a cold. It is certain that young subjects may continue to indulge in social pleasures involving active exercise, and that many older women will work hard for their families, until the disease has made great progress and produced prominent objective symptoms. The medical attendant will then be able to elicit little more history than that the patient has been recently confined, or has undergone some 'minor' gynecological operation, and that she has not felt quite well for a day or two. As a rule, however, there is much feverishness, and distinct rigors occur, with sharp pain in the pelvis. The pulse is rapid and softer than in pelvic peritonitis, and whilst the abdomen is less frequently tender than in that disease, vaginal examination gives far more pain. A hard immovable mass rapidly forms either on one side of the cervix, in front of it, or all round that part of the uterus. In all cases, it tends to spread laterally and upwards. This swelling, though not so circumscribed as a tumour, has boundaries which may be readily defined on bimanual palpation. In this respect it differs from pelvic peritonitis, where a distinct resistant surface is generally detected behind the cervix, yet no circumscribed swelling can be made out. For the diagnosis from hæmatocele see PELVIC HÆMATOCELE.

The hard mass of cellular tissue infiltrated with inflammatory products may project above the brim of the pelvis, so as to be plainly detected on pressure over the iliac fossæ, without introduction of the hand into the vagina. This condition can never occur in pelvic peritonitis. At this stage, suppuration or sloughing may occur. The uterus is firmly fixed in the pelvis, often from a very early stage. The disease tends to become chronic, especially if the

patient rise too soon after the more acute symptoms have subsided. In this case, indurated areas of cellular tissue remain, and render the patient subject to fresh attacks of inflammation.

Prognosis.—Pelvic cellulitis is seldom fatal. In the severe and sudden attacks which follow childbirth, the patient feeling very ill and anxious, will, as a rule, rest and obey advice. Hence, under such circumstances, complete recovery may occur in a few weeks, the indurated mass disappearing entirely. In sickly or careless subjects, abscess is very liable to form. The chronic forms are insidious, and often cause complications.

Treatment.—When the surgeon detects the indurated masses of infiltrated cellular tissue, he must carefully seek for evidence of suppuration. For the line of treatment to be followed if abscess form, the reader is referred to PELVIC ABSCESS. As long as there is no evidence of suppuration the patient must be left alone. Perfect rest in bed is absolutely necessary, and often proves in itself a complete remedy. Poulitices over the iliac fossæ and hypogastrium give great comfort. The rectum should be cleared of scybala by an enema, and an occasional saline purgative may be given, provided that evidence of peritoneal complications be absent. Above all, the patient must be kept in the recumbent posture for a week or two after the symptoms have disappeared.

ALBAN DORAN.

PELVIC HÆMATOCELE.—If blood escape from a pelvic organ it will flow in the direction of least resistance, and in this respect will imitate inflammatory exudations in the same region. As the inflammatory process is, however, very different from hæmorrhage, it is evident that the escape of blood into the cellular tissue of the pelvis cannot be precisely compared to inflammation of that tissue, which can offer great mechanical resistance to the blood; whereas its very substance is rapidly softened and otherwise altered by inflammation, so that it can no longer resist distension by exudations. Hence, hæmatoceles in the pelvic cellular tissue are rare, and cannot form large masses of semi-solid consistence; and many such masses, which once would have been considered as collections of coagula distending the cellular tissue, are really intra-peritoneal hæmatoceles.

In the pelvic peritoneum, as in the cellular tissue, hæmorrhage and inflammation must differ greatly. The former may be sudden, and then can go on freely,

with little mechanical check and imminent danger to the patient's life. When less violent or rapid, the blood will undergo the changes which always occur when that fluid escapes from its natural channels. The irritation of the fluid and its coagula, or, more likely, some morbid process existing previous to the hæmorrhage, and possibly its cause, sets up local peritonitis, and adhesions may form, cutting off the collection of blood from the rest of the peritoneal cavity. Lastly, the collection of blood may gradually disappear after undergoing well-known changes, or, under unfavourable conditions, it may become decomposed or excite suppuration in neighbouring parts. The surgeon should never overlook the fact that one of these unfavourable conditions may be uncalled-for surgical interference, or careless after-treatment when such interference may have been necessary.

Causes.—Any disease or accident, likely to cause hæmorrhage into the pelvis, may give rise to pelvic hæmatocele. During the process of ligature of the pedicle of a large ovarian cyst, a varix frequently forms on the proximal side, in the abundant cellular tissue found below the limits of the peritoneum in these cases, and it is highly probable that a true hæmatocele may form under these very circumstances. The writer has seen over a hundred cases where the proximal portion of the pedicle was found to be greatly distended with blood. No evil effects followed; hence it was impossible to prove, though reasonable to suspect, that in some of these cases the swelling was hæmatocele, and not simply varix. Extra-uterine foetation is the cause of the most serious form of pelvic hæmorrhage, and, when the bleeding is slow, a true pelvic hæmatocele may form.

The most frequent cause of pelvic hæmatocele is the rupture of some vessel, during the congestion of the pelvic viscera associated with the process of menstruation. Hence, the surgeon should never neglect to make most careful inquiries into the menstrual history of any case of solid or fluid deposit in the pelvis of a patient; and when a patient with such a deposit complains, before leading questions have been put to her, of an attack of severe pain during a menstrual period, the evidence in favour of hæmatocele is very strong. The source of the hæmorrhage is a much-disputed point, but it may arise from rupture of a vessel in the broad ligament, in the ovary itself, or under the mucous membrane of the Fallopian tube, or the tube may burst and bleed; lastly, most authorities main-

tain that the hæmorrhage may arise in the uterus and flow into the pelvic peritoneal cavity through the tubes.

Symptoms.—There is no disease that is occasionally so clear, and generally so obscure, as pelvic hæmatocele. A sudden attack of pain in the hypogastrium during a monthly period, followed by a swelling at the seat of pain, are the most characteristic symptoms. If the pain be preceded by a cessation of the menstrual flow, and succeeded by its reappearance for a day or two, the evidence of hæmatocele is still stronger. Distinct anæmia, with absence of fever for several hours or more after the onset of the attack, is also highly characteristic. The swelling, under favourable circumstances, will often become rapidly smaller, so as to leave little or no trace of its existence in a few weeks, and this without any history of escape of pus from the vagina, bladder, or rectum, or any symptoms of rupture of a cyst into the peritoneum. The surgeon must bear in mind this frequent course of a hæmatocele, for he is often called in some time after the acute symptoms have subsided. On the other hand, inflammatory changes may occur around the effused blood, and greatly obscure diagnosis. In the earlier stages, vaginal examination will often lead to the detection of a fluctuating swelling in Douglas's pouch or elsewhere in the pelvis; whilst, later, the swelling becomes firm and solid. This is often pointed out as the chief diagnostic sign, pelvic inflammatory exudations being hardest when most recent. But pelvic examination is not always easy at the onset of an attack of hæmatocele, nor does the surgeon generally see the case at that stage. As a rule, several of the symptoms above described will exist, but will be more or less masked, either by secondary complications or by a disease of which the hæmatocele is an effect.

Diagnosis.—The symptoms of pelvic abscess and pelvic cellulitis will be found in the articles on those diseases. Their onset is less sudden than the symptoms of hæmatocele; the phenomena of inflammation or suppuration exist from the first, and there is no necessary, though very often an accidental, connection with a menstrual period. The catamenial history is very important in diagnosis between simple hæmatocele and rupture of an extra-uterine foetal sac. See EXTRA-UTERINE FETATION. Retroversion of the pregnant uterus may produce sudden pain with shock, but bimanual palpation will show the true nature of this condition. When the effusion is chronic, it may be mistaken for old in-

inflammatory deposit, or even malignant infiltration, especially when the cervix uteri is lacerated and everted, and a sanious discharge flows from the uterine cavity. The physical characters of the swelling and the importance of the menstrual history have already been noted.

Prognosis.—When the early symptoms are very marked, the disease may be rapidly fatal, since the hæmorrhage is then considerable; and when they abate, it must be remembered that they may recur at the next period. A large proportion of typical cases recover, especially when rest has been enforced. The collection of blood may undergo suppuration or decomposition, producing characteristic symptoms.

Treatment.—It is certainly good surgery to leave most cases of pelvic hæmatocele alone, but there always remain some in which active treatment is necessary. When the surgeon is summoned directly the acute symptoms appear, the abdominal pain will induce him to explore the abdomen, and the swelling will be detected; and it need hardly be added that he must explore the pelvic cavity by bimanual palpation. The detection of a fluctuating swelling, almost invariably in Douglas's pouch, certainly could not induce him to puncture it. Perfect rest for several days must be enforced, opiates will in many cases prove beneficial, and ergot should be administered in small doses at intervals of six or eight hours. A good preparation of that drug for this purpose consists of half a drachm of the iron-muriated tincture, with twenty minims of rectified spirit, to be taken in a wine-glassful of water. It is less likely to decompose than the liquid extract freely dissolved in water, and thus keeps its strength for days. If the symptoms of internal hæmorrhage be very marked, the surgeon may, after full deliberation, be induced to take upon himself the grave responsibility of abdominal section, with a view of securing the bleeding vessels. Such a course is certainly justifiable if he have no experience in abdominal surgery; but must not be forgotten that to handle the uterine appendages, when they are not engaged, especially when they are embedded in coagula, is a far more difficult task than to remove an ovarian cyst. If the hæmorrhage be found to proceed from the ovary, that organ must be amputated, and when blood is seen flowing from a rent in one of the ovarian veins, that vein must be secured; but, as a rule, the hæmorrhage is best checked by removal of the uterine appendages on the affected side. No

operation of this kind should be attempted until there is strong evidence that the source of the hæmorrhage is not in the uterine cavity. See OÖPHORECTOMY.

When the case is more chronic, the patient must be careful to refrain from exertion during each period, when the bleeding may recommence. Should the swelling remain undiminished in size, it must not be interfered with without due deliberation. Indeed, it is best to leave it alone altogether, unless symptoms of suppuration or decomposition of the clot make their appearance. Abscess may form near a hæmatocele and acquire communications with it, ultimately bursting on a free surface, either in the rectum or in some part of the genito-urinary tract. When any such complication is suspected, the swelling may be opened in its most dependent portion. The aspirator is unadvisable; a large trocar is best for the purpose, and it is not safe to break down the clot with the finger, as thus adhesions may be torn, endangering the peritoneum and neighbouring organs. Should the abscess have burst, the aperture in the mucous membrane of the vagina or rectum must be cautiously enlarged, if the mixture of pus and coagula cannot escape freely. The vagina should be frequently washed out with antiseptic lotions, thrown up with gentleness and caution.

ALBAN DORAN.

PELVIS, Injuries of the.—These are contusions and fractures. *Contusions* of the pelvis are not different in effect from similar injuries in other parts of the body; therefore no special description of their symptoms or treatment is requisite. They sometimes cause considerable extravasation of blood. If this be subcutaneous it cannot be mistaken, and in most cases is speedily absorbed; but if absorption be tedious, aspiration and compression may be employed. If the extravasation be beneath the gluteal fascia it may be mistaken for an abscess, but the temperature chart of the patient will show whether acute suppuration is occurring or not. In doubtful cases, aspiration may be used to decide the nature of the case.

With respect to fractures, the pelvis may be regarded as a girdle of bone; for the articulations at the sacro-iliac synchondroses and the symphysis pubis are so close and rigid, that separation of these parts may be practically regarded and treated as fracture, although it is technically a dislocation. Each of the component bones of the pelvis may be fractured independently of the others.

FRACTURES OF THE OS INNOMINATUM.—The anterior and superior part of the ala of the ilium may be fractured by falls against some hard surface, or by severe blows, or by the patient being run over. If uncomplicated, it is not of much importance. The patient will experience pain on movement, especially in changing from the recumbent to the sitting, or from the sitting to the erect position, or in violent expiration, such as coughing, sneezing, &c. The local pain and the mobility of the fragment will indicate the nature of the injury. Rest in the recumbent posture, and the application of a well-adjusted pelvic belt, with the interposition of cotton-wool for the protection of the skin over bony prominences, will suffice for treatment.

In young persons, the epiphysis of the crista ili is sometimes partially detached by violent muscular efforts. The history of the case, the local pain, and the exclusion of all other possible causes, must serve as indications for the diagnosis of this rare accident. The treatment will be the same as for fracture of the ala of the ilium. The anterior superior and inferior spinous processes of the ilium are occasionally detached by violent action of the sartorius and rectus femoris muscles. The treatment will be rest in the recumbent posture. Probably some local but unimportant deformity will result.

FRACTURES OF THE ACETABULUM are attended with more serious consequences. Sometimes, a fall on the feet from a height will result in fracture of the upper margin of the acetabulum and dislocation of the femur on to the back of the ilium. The recurrence of the dislocation after reduction will indicate the nature of the injury, which must be treated, after reduction of the dislocation, by the application of a long splint and extension by a weight and pulley, as in fracture of the thigh. Permanent shortening of the limb will probably result.

Sometimes, the floor of the acetabulum is detached from the rest of the bone and driven into the pelvic basin. The head of the femur may be impacted in the opening. This injury may result from falls on the great trochanter or on the feet. If in such an accident the head of the femur be impacted, the shortening of the limb and the immobility when the patient has been anaesthetised might suggest, in the absence of any other cause, the nature of the injury. But if there be no impaction, a certain diagnosis would appear to be impossible. These cases are, however, very rare, and the general symptoms would indicate

the necessity of rest and, probably, of extension by weight and pulley.

The os innominatum may be fractured into its three component parts. This may be caused by a fall on the great trochanter, or possibly on the head. The writer has seen two instances of this fracture which appeared to have been caused by falls on the head. Since the base of the skull can certainly be fractured in consequence of a fall from some height upon the feet, it is not improbable that the innominate bone may be fractured by being forced against the femur, as well as by the femur being forced against it. To adopt Koenig's apt illustration, the head of a hammer can be driven on to the handle, or the same result may be obtained by striking the reverse end of the handle, vertically, against some resisting surface. This fracture of the innominate bone is usually complicated by other fatal injuries. If not, union may result, as museum specimens prove, which have subsequently been obtained from subjects who had previously sustained this injury. Permanent lameness would be inevitable. The diagnosis of the injury would be very difficult. Mobility of the fragments would render it certain, but the fragments are usually interlocked. The general symptoms would indicate rest and, probably, extension of the corresponding lower extremity, as the most suitable treatment.

The SACRUM may be fractured by blows, kicks, or falls from a height in a sitting posture. Such a lesion involves risk of inflammation of the membranes of the spinal cord, or of injury to the sacral nerves and paralysis of the parts supplied by them. The treatment would consist in rest in the horizontal position, with careful adjustment of pillows so as to prevent any pressure on the part. It occurs very rarely. The writer has seen one instance of it. A sailor had fallen from a mast on deck, in a sitting posture, and, unfortunately for him, on a cocoa-nut. His sacrum was extensively comminuted. The accident happened at sea. Several months later he was admitted into the London Hospital under Mr. Curling. He had several fistulae over the sacrum and in the perineum, leading to necrosed bone, and, as faeces escaped by many of these, the rectum had certainly been implicated in the injury. The condition of the patient prevented any attempt at operative interference, and he was discharged as incurable.

The COCCYX may be fractured by similar causes or in parturition. The patient will experience pain in movement and during

lefecation. The introduction of a finger into the rectum will detect any malposition of the fragment. When this has been reduced, the patient must be kept at rest until union has taken place.

The PELVIS, regarded as a bony girdle, may be fractured in consequence of severe compression, as by the passage across it of the wheel of a heavily-laden vehicle, or in some railway or similar accident. Solution of continuity usually occurs at both sacro-iliac synchondroses, the symphysis pubis, and the horizontal rami of both pubic bones, immediately internal to the ilio-pectineal eminences. The ascending rami of the ilia are also often broken. In some cases the force acts diagonally, so that only one synchondrosis is torn open, and the horizontal ramus of the opposite pubic bone fractured at the usual place. More rarely, the injury may be limited to the bodies and crests of both pubic bones. This may possibly result from spasmodic contraction of the abdominal muscles, as well as from direct violence. The history of the case, the inability of the patient to walk, and pain on attempting to move the lower extremities will indicate the nature of the injury. Slight pressure on both halves of the pelvis may detect mobility, or cause great pain to the patient. Absence of both these signs, and especially of the latter, might encourage the surgeon to hope that it was a case of contusion rather than fracture. Minute investigation as to the extent of the injury is not advisable. The injury, uncomplicated, and if not immediately fatal from shock, would not be of much greater importance than other severe fractures. But it is almost always complicated with serious visceral lesions.

Attention should at once be directed to the condition of the bladder and urethra. A full-sized silver catheter should be cautiously introduced, if possible, into the bladder and, if the urine be tinged with blood, should be tied in, and connected with a receiver containing carbolised water. An exhausted india-rubber tube, so that the urine may flow at once from the bladder to the receiver. But if the urethra be torn across, or if the bladder be ruptured, the appropriate treatment for these lesions must be adopted. See BLADDER, Rupture of the; URETHRA, Injuries of the. Laceration of the liver, spleen, kidneys, or intestines, injuries to the thorax, or fractures of the bones of the upper and lower extremities, frequent complications. The prognosis is very unfavourable, and the treatment, so far as the fracture of the pelvis is concerned,

will consist in rest, with support from suitably adjusted pillows.

JEREMIAH MCCARTHY.

PEMPHIGUS (*Synon.* Pompholyx).—

A rare disease of the skin, characterised by the appearance of bullæ in successive crops on any part of the cutaneous surface, and occasionally on the adjacent mucous membranes. Nothing is known with certainty as to its causation; it is met with in all climates and at all seasons of the year, is more frequent in children than in adults, and is perhaps a little commoner in men than in women; it is not contagious. The persons attacked by it are sometimes exhausted by chronic diseases of various kinds, or by insufficient food and bad hygienic conditions, but it often occurs in those whose general health appears to be perfect; it is sometimes congenital, or nearly so, and has been observed to be hereditary on rare occasions. It is probable that the nervous system is directly or indirectly implicated, and evidence is accumulating which favours this view; thus mental suffering, hysteria, sciatica, epilepsy, and insanity have been noted as antecedents, and a case of herpes zoster, which followed nervous injury, has been observed to become transformed into generalised pemphigus (pemphigus neuriticus). Pregnancy and parturition have often been noted as associated conditions; and, further, pyæmia, chronic Bright's disease, and other states in which toxic matters are absorbed into or retained in the blood, have been considered as causes. It is probable that, in many of the above instances, the bullous eruption which occurs should not be admitted as true pemphigus. The blebs which appear in leprosy and syphilis should certainly be excluded. See *Herpes Gestationis* and *Herpes Iris* under HERPES; *Erythema Exudativum*, &c., under ERYTHEMA.

Pathologically, the disease may be placed among angioneuroses of the skin, a loss of tone of the blood-vessels, with more or less inflammatory disturbance, being accompanied or immediately followed by a rapid effusion of serum which raises the epidermis in a blister; hence the bullæ of true pemphigus, being due to a sudden epidermic cleavage, are unilocular, and their roof is formed by the whole epidermis, the floor consisting of the corpus papillare of the corium with a few adherent remains of epidermis, chiefly of the deepest (cubical) layer. More rarely, the splitting takes place immediately below the stratum granulosum.

the parts above which then form the roof. This form of bulla, which is not due to inflammatory changes in the epidermis, is thought to depend on a diminished power of resistance to pressure by fluids in the cells of the stratum spinosum (Malpighii), and the whole process has received the name *Acantholysis*. The bullæ which form as a result of inflammation arise in a different manner: by gradual changes in the cells of the rete, leading to vacuolation and vesiculation of individual cells, the vesicles gradually enlarge and become confluent with their neighbours, so as ultimately to give rise to irregularly loculated large cavities containing serum; in short, an inflammatory bulla is no more than an accidentally gigantic vesicle. The contents of the bullæ of pemphigus are serum, with more or less admixture of coloured corpuscles and leucocytes; the fluid contains a trace of urea, and its reaction is at first neutral and subsequently alkaline. Necropsies of pemphigus have revealed no constant visceral lesions; but, recently, sclerotic changes in the spinal cord, and degeneration of the peripheral nerves at the seat of eruption, have been noted.

The greatest variability in the size, aspect, and distribution of the bullæ, in the duration of the disease, and in the severity of the symptoms, is characteristic of pemphigus, and hence authors have overloaded medical nomenclature with a superabundance of terms. It is not necessary to recognise more than two forms, pemphigus vulgaris and *P. foliaceus*; these are well marked, but the multitude of other names only deserve incidental mention as subvarieties.

1. PEMPHIGUS VULGARIS.—As already stated, the bullæ appear in successive crops, and may arise upon any part of the surface of the skin; they are perhaps commonest on the limbs, when they are roughly symmetrical. They are developed either upon reddened discoid spots or, more commonly, upon normal skin, and either retain their original size or grow, and sometimes become confluent. An outbreak of blebs is sometimes associated with pale red spots and wheals, which die away without giving rise to bullæ. A fully developed bulla is characterised by a rounded or oval shape, which becomes irregular when confluence has occurred; its size varies from that of a pea to a hen's egg or more; the base is surrounded by a faint and narrow erythematous zone; the walls are tense and shining, and the whole blister projects considerably above the surface, sometimes as much as an inch. The contents are at first transparent and

colourless, turning to citrine yellow; later, they become turbid and milky from admixture of pus-corpuscles; sometimes the colour varies from pale cherry to dark red, owing to admixture of blood (*P. hæmorrhagicus*), not necessarily in severe cases. In about three days to a week a bulla has either gradually shrivelled and dried up without rupture, or, less frequently, it has burst; in either case, a thin crust of old epidermis with dried exudation, and blood, if present, occupies its site, and after its detachment leaves a bluish-red macula corresponding to the base of the bleb; this is usually completely covered with young epidermis, and gradually fades away after becoming slightly pigmented. The bullæ appearing simultaneously vary in number from a few to a hundred or more, and may be distributed irregularly over a wide surface (*P. disseminatus*) or grouped (*P. confertus*). In rare cases a central bulla is surrounded by a more or less distinct ring of others (*P. circinatus*), and irregular serpentine figures may be produced by confluence (*P. gyratus*, *serpiginosus*); occasionally only a single bulla of large size appears at a time (*P. solitarius*). It is usual for fresh bullæ to make their appearance before the crusts and maculæ due to the previous outbreak have faded; therefore, in a characteristic case, stains, crusts, and blisters are present at the same time.

The interval separating the outbreaks is variable; sometimes, it is so considerable that an incautious observer may conclude the disease to be at an end, and at others crop after crop appears with barely appreciable intermission (*P. diutinus*). The constitutional symptoms vary with the extent of skin affected, the frequency of the outbreaks, and the duration of the disease. An outbreak of some severity begins with shivering, malaise, and fever, the rise of temperature being sometimes considerable but usually very moderate and of short duration; in mild cases the temperature is normal (*P. apyreticus*); during the continuance of the eruption, thirst, loss of appetite, and above all loss of sleep, are prominent symptoms, the latter being due to the itching, tingling, or burning, which are more or less marked. Itching is sometimes very severe. The bullæ are then destroyed by scratching, leaving excoriations. There is much associated urticaria and brown pigmentation, and eczema may appear as a complication.

In favourable cases, the disease may at an end in from two to six months, the bullæ becoming fewer and fewer with each

attack, and finally ceasing to be produced. The patient may then remain free for the rest of life, or fresh attacks may occur after many months or even years. In children, the whole process is more active and rapid and the fever higher, so that in some cases an end is reached in from two to three weeks (*P. acutus*, *febrilis*). In one or two instances a similar rapid course has been noticed in adults, but in the vast majority the disease is chronic. In rare cases, the successive crops of bullæ make their appearance in the same situations on each occasion (*P. localis*); they are then few in number, and are chiefly limited to the backs of the hands and feet and the extensor surfaces of the arms and legs, very much in the positions of psoriasis. In the writer's experience such cases are continental or nearly so, and extremely chronic, lasting for many years in spite of treatment; they are further characterised by the development of traumatic bullæ, a blow or other injury being followed by the appearance of a bleb, which is often hæmorrhagic. Both in these and in ordinary cases in which the eruption appears on the hands and feet, the nails often become affected in a characteristic manner. Apparently a bulla forms immediately under the nail, which becomes detached from the matrix, and of a dead white colour; it is ultimately shed, and the new nail is rough, irregular, and badly developed. Severe cases of pemphigus are characterised by a copious eruption, large size and confluence of the blebs, severe itching and burning, and very short remissions between the outbreaks; exhaustion and a fatal result may follow, although this is fortunately by no means invariable. The gravest cases are marked, in addition, by rupture of the bullæ, leaving excoriated or ulcerated surfaces (*P. alignus*) on which sloughs may form (*P. ingranosus*). Cases of this kind are extremely rare. When the mucous membrane of the mouth is attacked, bullæ cannot be recognised on inspection, as they rupture once, and the epithelium is soon detached in white flakes, under which a rounded excoriated spot is left. The process may extend to the pharynx and cause much difficulty and pain in swallowing, increasing the gravity of the prognosis. The mucous membrane of the conjunctiva and vagina may also be affected.

2. PEMPHIGUS FOLIACEUS.—This exceedingly rare affection is distinguished by the imperfect development of the bullæ, which are flaccid, contain a small quantity of thin serous fluid, and rupture with the greatest

ease; the adjoining epidermis becomes undermined and loosened, so that detachment occurs over a considerable area. The affected cuticle separates from the skin incompletely, and becomes shrivelled and rolled up at the edges, presenting an appearance which has been likened to flaky pie-crust. The subjacent corium is red and excoriated, the fluid oozing from its surface drying up into thin varnish-like crusts, under which a new epidermic layer has no time to consolidate, as it is at once again detached by a continuance of the process as fast as it is formed, and has then not sufficient power of resistance to form a bleb, but is shed as a thin scale. The process gradually extends until the greater part, or even the whole of the skin, is implicated. The surface then shows no bullæ, but is traversed by fine cracks, between which there are thin, flaky, more or less adherent crusts or raw oozing spots, and a nauseous odour exhales from the skin; the hair falls off largely, the eyelids become ectropic, and the nails thin and brittle. The patient loses appetite, suffers considerable pain, especially on movement, and gradually becomes emaciated and cachectic. Fever, which is slight at first, becomes gradually continuous, exhaustion supervenes (more rapidly when the throat is affected), diarrhoea may set in, and a fatal termination usually results. The disease may appear as such, or may develop from a long-continued pemphigus vulgaris, and is always exceedingly chronic, usually lasting many years. Although the prognosis is extremely grave, occasional instances of recovery have occurred.

Diagnosis.—The diagnosis of pemphigus does not depend upon the recognition of bullæ, which may form under a great variety of conditions, but upon the fact that they are chronically recurrent, appearing in successive crops, and that the great majority arise upon normal skin. If this be borne in mind, there will be no difficulty in distinguishing the disease from bullous urticaria, vesicating erythema, erythema (herpes) iris, and erysipelas. Bullæ may occur in scabies and in eczema, but the history and concomitant lesions of these affections are such as to render the diagnosis easy. In anæsthetic leprosy the bullæ are merely part of a constitutional disorder, with well-marked symptoms of its own, while syphilitic bullæ dry up into thick crusts, covering an ulcerated surface. The blisters which are due to friction, as from rowing or from ill-fitting boots, and those which arise from burns and scalds,

need barely be alluded to, while those which are produced by the fraudulent application of blisters and irritants to the skin are soon detected, in a suspicious case, by isolation and watching. Pemphigus foliaceus, after bullæ have ceased to be produced, may bear a close resemblance to general eczema rubrum, from which, however, it differs in the history, in the character of the fluid secreted, which is much thinner in pemphigus and does not stiffen linen, and in the greater severity of the constitutional symptoms. Some cases of pityriasis rubra (exfoliative dermatitis), and even of nearly universal psoriasis with flaky desquamation, have a very similar appearance; but, again, the history, the absence of bullæ at any previous period, the dryness of the surface exposed, and the much more profuse and easy detachment of thinner paper-like scales, will be sufficient distinctions.

Treatment.—The treatment of pemphigus differs according to the stage of the disease. When there is high fever, the patient should be kept in bed and the strength supported by fluid and nutritious food, with stimulants if necessary; a saline mixture with a small dose of antimonial wine (℥v. to x.) may be at first administered, but should not be long continued, to avoid depression; as the temperature falls quinine should be given, or it may be employed from the first; opium, to allay irritation and procure sleep, is a valuable remedy. As soon as a normal temperature is reached, arsenic should be begun and steadily continued. Although it is not curative in all cases, there can be no doubt that it gives good results in the great majority, if persevered in for a long time, and in full doses—say ℥x. of liquor arsenicalis three times a day, gradually reached; even larger doses may be given if it does not disagree, especially in combination with a little opium. When the patients are emaciated and anæmic, cod-liver oil and iron should be always employed, the latter with quinine as a rule. The local treatment is very similar to that employed for a burn—viz. the application of linimentum calcis on rags and envelopment of the parts in cotton-wool. A carbolic lotion or other anti-pruritic may be used when there is much itching, but the copious application of a dusting powder of starch and oxide of zinc, or of oleate of zinc, is to be preferred, as it is less troublesome and equally soothing. If the bullæ are closely packed, they may be pricked as soon as they appear, to relieve tension, and this should also be done if they show a tendency to spontaneous

rupture; but in ordinary cases no such interference will be necessary. The thin crusts, which form by the desiccation of the blebs and their contents, should not be detached, but allowed to come away spontaneously. If any excoriated surface be left, it should be protected by zinc ointment, or some more stimulating remedy may be applied if it does not heal readily. Very small bullæ may be sometimes checked in their growth or caused to abort, by being painted over with a solution of nitrate of silver in spirit of nitrous ether (gr. xv. to fʒj.) as soon as they make their appearance. When the mucous membrane of the mouth and pharynx is affected, a mouth-wash of chlorate of potash should be used, or the parts may be painted with honey of borax; if the affection is so severe as seriously to interfere with swallowing, the employment of nutrient enemata may be necessary for a time. The treatment of pemphigus foliaceus is unsatisfactory; quinine and arsenic may prove serviceable, but nearly always nothing can be done beyond supporting the patient's strength by good food and stimulants, and the employment of local palliative measures, among which the chief is the continuous warm or tepid bath; in this patients may be kept for months with comfort and advantage. JOHN CAVAFY.

PENIS, Amputation of the.—This operation may be performed by the écraseur, by the galvanic cautery, or by the knife. The use of the écraseur presents little advantage, and can only be advised in exceptional cases, when there is reason to expect a tendency to severe hæmorrhage. The galvanic cautery, when it can be had, is a most effective instrument for this operation, care being taken not to use the wire at too great a heat, or to divide the tissues too rapidly, as in either case hæmorrhage is likely to occur. When the amputation is completed, the urethra should be slit up for about half an inch with a pair of fine blunt-pointed scissors, and the edges attached by fine silk or catgut sutures to the skin and corpora cavernosa.

By far the most common method of amputating the penis is, however, with the knife. The old plan of removing the organ by a single sweep of the knife, and then slitting up and securing the edges of the urethra, has certainly the advantages of great simplicity and rapidity of performance, and in some cases, where the extension of the disease requires that the amputation should be performed as high up as possible, it is still to be recommended. But an im-

provement has been made in the operation with the object of securing the projection of the urethra beyond the stump, and thus avoiding the exceedingly troublesome retraction of the passage, which was not infrequently the result of the old operation. The steps of this operation are as follows: A tape is first firmly tied round the root of the penis, or Clover's clamp is applied at the same spot, by which means the operation is rendered bloodless. The penis is then drawn well forward by the left hand, care being taken not to overdo this, and thus leave too little skin to cover the stump. The next step in the operation is so to cut through the corpora cavernosa and the corpus spongiosum as to leave the latter, with the urethra, projecting half an inch beyond the former. This may be effected in two ways. First, by introducing a narrow straight bistoury between the corpora cavernosa and the corpus spongiosum, turning the edge of the knife upwards, and dividing the corpora cavernosa by a single sweep. The corpus spongiosum is then cut through by a downward sweep of the knife, half an inch nearer the glans. The other method, which is perhaps on the whole the easier, is as follows:—A full-sized catheter is introduced in order to define accurately the position of the urethra. A circular incision is then made through the skin only. The corpora cavernosa are next divided from above downwards, care being taken not to wound the corpus spongiosum. This accident will be prevented by the presence of the catheter acting as a landmark. The catheter is now withdrawn, and the corpus spongiosum, being put well on the stretch, is divided half an inch lower down.

Whichever method is adopted, the operation is completed by slitting up the urethra on the dorsal aspect, its lower edge being stitched to the skin below, and the upper portion to the corpora cavernosa. Fine curved needles in a needle-holder will be found most convenient, and very fine silk or catgut for the sutures. Before the tape or clamp is loosened, careful search should be made for the open mouths of all vessels. The arteries of the corpora cavernosa, the dorsal arteries, and the artery of the septum may generally be seen and at once secured. The pressure is then taken off, and any further bleeding points secured. The surface of the wound should be well dusted over with iodoform, and the parts dressed with lint steeped in a 1-40 solution of carbolic oil. The whole should be covered by a wad of tenax, secured in its

place by a T-bandage. The after-treatment is of the simplest: for the first few days care should be taken to prevent the urine, as much as possible, from passing over the raw surface of the wounds. The free use of iodoform, or an ointment made with iodoform, eucalyptus, and vaseline, is the best dressing. The fine sutures that have been inserted may be left to themselves.

It occasionally happens that the disease has so far advanced as to necessitate a more severe and complicated operation than either of those already described. In fact, it may be needful to remove the entire penis, including the attachment of the crura to the pubic arch. This operation, suggested by Mr. A. Pearce Gould, is thus performed. The patient being placed in the lithotomy position, an incision is made with a scalpel along the whole length of the raphé of the scrotum. Then, with the finger and the handle of the scalpel, the interspace between the two halves of the scrotum is separated down to the corpus spongiosum. A catheter is then passed down to the triangular ligament, serving as a guide for the passage of a knife between the corpora cavernosa and the corpus spongiosum. The catheter is now withdrawn, and the corpus spongiosum with the urethra is cut through.

The next step is to complete the separation of the urethra from the penis, and to carry the separation as far back as the triangular ligament. The removal of the penis is then effected by prolonging the incision, first made in the median line, round the root of the penis, dividing the suspensory ligament, and exposing the insertions of the crura. These attachments are separated from the pubic arch by a periosteal elevator. The orifice of the urethra is then slit up for half an inch, and its edges stitched with fine sutures to the skin at the posterior extremity of the scrotal incision. The rest of that incision, after all vessels have been secured, is then brought together with sutures, ample means of drainage being afforded. The result of this operation is that the urethral orifice is kept behind the scrotum, and the urine is prevented from dribbling over the skin of the surrounding parts.

PAUL SWAIN.

PENIS, Diseases of the.—For congenital malformations, see *Epispadias* under *Ectopia Vesicæ*; *Hypospadias*; *Phimosis*.

Cancer of the penis is for the most part epithelial in its character. Cases of carcinoma of the corpora cavernosa are occasionally met with, but very rarely. Epithelioma of the penis assumes one of two

forms. It may appear as a flat, tubercular mass, with a hardened base, situated on the glans or in the sulcus formed by the junction of the glans with the prepuce, or on the inner surface of the prepuce itself. It may also commence in the urethra. After a time the surface of the tubercle cracks, and exudes a fetid serous discharge. Ulceration now sets in, spreading rapidly upwards on to the penis, and thence, if the disease is not dealt with, to the scrotum and perineum. The base of this ulceration is greyish in colour and uneven, the edges being frequently everted. The other form of epithelioma assumes the character of a warty growth, and is, in fact, in its early stages, somewhat difficult to distinguish from the ordinary warts which are so frequently found on and around the glans and beneath the prepuce. The presence of a hard base, of ulceration with its attendant fetid discharge, and a tendency to hæmorrhage at the slightest touch, will leave little doubt as to the malignancy of the disease.

Another confirmatory symptom will be the enlargement of the glands in the groin. The rapidity with which the glands are affected varies with the situation of the original disease. If the epithelioma is situated on the corona glandis or beneath the prepuce, the moisture of the parts seems to favour the progress of ulceration, and, under these circumstances, the glands become more rapidly involved in the disease. On the other hand, an epithelioma on a more exposed part of the penis will affect the glands with less rapidity. One other difficulty of diagnosis may occur—viz: whether, in its earlier stage, the disease may not be simply the induration of a syphilitic sore. Doubt as to this, however, cannot long remain. The history of the case, and the failure to obtain improvement under specific treatment, will reveal the true nature of the case. The age, too, of the patient will be an important aid to diagnosis. Epithelioma of the penis is seldom found before the age of forty-five, and from that to seventy is the period of life when it more usually occurs.

Causes.—It is asserted that congenital phimosis is a predisposing cause of epithelioma, owing to the irritating effects of the retained secretions. The fact that the Jewish community is peculiarly free from this disease seems to favour the statement. Venereal warts, chancres which remain long unhealed and are subject to much irritation, the induration in the scar of an old chancre, may each and all of them lead to epithelioma. Injuries to the penis, espe-

cially laceration of the frænum, may also be the starting-point of the disease.

Treatment.—In few diseases is the policy of delay more to be deprecated than in epithelioma of the penis. As soon as the condition comes under notice, even if there is considerable doubt as to its real character, removal of the disease should be at once undertaken. In the case of warty growths, they should be destroyed with nitric acid, or the portion of skin from which they sprout should be excised with the knife. So, too, the tubercular form of the disease should be freely excised, provided the surrounding tissues be not too infiltrated. If the patient is the subject of phimosis, the prepuce should be at once slit up and the diseased surface exposed. *See PHIMOSIS.* Careful search for affected glands should be made, with a view to excision. In fact, it is of the utmost importance to deal with these glands at the earliest possible period. They early become so infiltrated with the disease and matted together that a clean removal is next to impossible, and extensive ulceration of the skin over them soon follows. When the local disease is beyond the chance of removal, amputation of the penis becomes needful, the division of the organ being made as far as possible from the site of the growth, and in advanced cases it may even be needful to remove the entire organ. *See PENIS, Amputation of the.*

Tumours of the Penis.—Fatty, nævoid, sebaceous, and fibroid tumours are occasionally met with on the penis, and require no particular description. In the case of the last, the question of recurrence should be considered. Mr. Beck has recorded a case in which he removed a fibrous tumour from the base of the glans penis. It recurred after two years, necessitating the amputation of the organ. A condition of preputial hypertrophy allied to elephantiasis is occasionally met with. Its treatment consists in the free removal of the redundant tissue.

Inflammation of the Corpora Cavernosa.—There sometimes occurs, in men of middle age, a localised, chronic enlargement in the sheath or erectile tissue of one or both corpora cavernosa. Mr. Prescott Hewett has described the condition in the history of a case recorded in the *Clin. Soc. Trans.* vol. vi.: 'In the corpus cavernosum were four nodules, three on the left side and one on the right, varying in size from a pea to that of a French bean; they were perfectly circumscribed, hard to the touch, knot-like, and painless when handled.' These cases seem to be

associated with the gouty diathesis, and occasionally may be traced to some slight injury. They are, in point of fact, cases of phlebitis. There is a general concurrence of opinion that little or no treatment is called for. Thrombosis of the dorsal vein is also met with under similar circumstances, and gradually disappears spontaneously.

Gangrene of the Penis.—Gangrene of the penis is generally the result of some acute inflammatory process. Acute inflammation of the prepuce following on gonorrhoea or chancre, the constriction of a paraphimosis, or the more immediate effect of a ring or ligature placed round the organ, may be the exciting causes. It is generally met with in patients whose health is broken down, and is of the moist variety, though occasionally dry gangrene follows an attack of fever. The treatment should be directed first to remove all constriction, by slitting up the prepuce in phimosis, and relieving the constricting band in paraphimosis. See PHIMOSIS; PARAPHIMOSIS. Then, if needful, free incisions should be made into the substance of the penis, and warm applications be continuously employed. Meanwhile, the general condition would require a stimulating and nutritious diet, with the administration of quinine and opium freely. As the time for the separation of the slough approaches, hæmorrhage not infrequently takes place, and, it is needless to say, is but ill borne by the patient already enfeebled by disease. During the process of cure, the contraction of the parts may so affect the urethra as to require attention. It should be slit up for half an inch, and stitched to the neighbouring skin, as directed for amputation of the penis.

Warts on the Penis.—The presence of warty growths on the penis is not infrequent, as the result of venereal infection or want of cleanliness. They are found on the skin outside the prepuce, fringing its orifice, on the mucous membrane between the skin and the glans, on the glans itself at the orifice of the urethra, and even within that canal. They are contagious. The most effectual method of treatment is removal with the scissors. The bleeding is sometimes rather free, but easily arrested by the use of very hot water and compression by strips of dry lint. In less severe cases, simply powdering over with calomel or oxide of zinc, with strict attention to cleanliness, will effect a cure.

Herpes is found on the prepuce and corona glandis as the result of local irritation or gastric disturbance. See *Herpes Progenitalis* under HERPES. PAUL SWAIN.

PERFORATING ULCER.—This affection is not exactly an ulcer. It is usually met with as a sinus-like aperture on the plantar surface of the foot, the sinus, if of any duration, leading down to dead bone. The opening is most frequently single, and situated over the metatarso-phalangeal joint of the great toe; but two or three openings may be met with—e.g. over the heads of the fourth and fifth metatarsal bones. Both feet may be affected. The orifice of the sinus usually gives vent to but slight discharge, is surmounted by but few granulations, is situated in what has been a corn, and surrounded by a flattened whitish-yellow area of greatly thickened epidermis. In addition to necrosed and fifth metatarsal bones, the subjacent joint may be affected, together with other articulations not in direct communication with the sinus. The tissues surrounding the sinus are usually not sensitive, and loss of sensation may be detected over the areas of one or more of the cutaneous nerves of the foot or leg. This anæsthesia may be accompanied by profuse and fetid sweating. More rarely anæsthesia is not observed, but cutaneous hyperæsthesia is present in the leg and foot. But, though the surrounding tissues may be insensitive, the patient is usually crippled by the great pain experienced in walking; he is furthermore liable to attacks of erysipelas and eczema.

Pathology.—In a large number of cases of perforating ulcer some degenerative nerve-lesions may be expected to be at the root of the matter. How many such lesions may cause perforating ulcer is not known; nor, in the case of those which are recognised, is their connection with the ulcer exactly understood. At present we may divide such nerve-lesions into two main classes—peripheral and central. Thus, in some the tibial nerves have been found much thickened with addition of connective tissue in the peri- and endo-neurium, and with multiplication of nuclei. Near the ulcer the ultimate nerve-fibrils are nearly obliterated, and farther from it the smaller fibres, which some authors consider to be sensory and nutrient, are found diminished in number.

In other cases the degeneration would appear to be central. The most interesting of these are the cases where patients with perforating ulcer are found to suffer from the lightning pains and anæsthesia in the lower limbs, the gastric and intestinal crises, the deficient motor co-ordination, and the diminished patellar reflex of locomotor ataxia. Perforating ulcer usually appears in the later stages of this disease; more rarely, it is noticed long before the locomotor

troubles. As this subject becomes better known, it may be expected that this disease may be proved to be associated with other lesions of the cord, spinal ganglia, or nerves, or with compression and laceration of large nerve-trunks. But, as yet, perforating ulcer is involved in much obscurity, and it is greatly to be desired that practitioners who may meet with cases should record them carefully, and, at every possible opportunity of amputation or post-mortem examination, preserve the foot with the nerves and spinal cord for examination.

Treatment.—Long-continued rest, and removal of the diseased bone, may, and often do, bring about a cure; but this is only temporary, the disease returning even after two or three years. When once the condition is declared—i.e. when one or more perforating ulcers with any anæsthesia are present—amputation of the foot should be resorted to. As it is often the terminal portions of the tibial nerves which are chiefly affected, Syme's amputation will in many cases remove the disease; if this recur in the stump, Teale's amputation, sawing the bone in the middle of the tibia, or amputation by lateral flaps through the tubercle of this bone, must be resorted to. Where the patient refuses amputation, or where this step is contra-indicated, imperfect rest and relief from pain will be secured by using a knee-rest and a well-padded shoe.

W. H. A. JACOBSON.

PERICARDIUM, Wounds of the.—These wounds may be produced by an external penetrating agent, or by the rough end of a fractured rib or sternum. They seldom occur alone, being generally associated with wounds of the heart, or of some important organ in the mediastina, such as the internal mammary artery, the œsophagus, &c. In those rare cases in which this membrane is alone wounded, the diagnosis can scarcely be satisfactorily established at first. The signs will be those of pericarditis—viz. increased precordial dulness, the pericardiac to-and-fro friction-sound, a small hurried pulse, and generally considerable dyspnœa. The pericardiac friction-sound may become lost if the precordial dulness increases much in extent. This is due to the effusion of blood, serum, or pus within the pericardium; should the case go on favourably, the sound may be heard again after some days from the gradual absorption of these products.

The indications for treatment will be similar to those for wounds of the other thoracic viscera. At first, it will most pro-

bably be doubtful whether the pericardium is alone wounded. But as the line of treatment is practically the same, this will not be of any great consequence. These indications will be treated of under HEART, Rupture and Wounds of the.

It may, however, be said here, that there is one condition of uncomplicated wound of the pericardium, in which special treatment is required. The pericardium may become over-distended by fluid, so much interfering with the heart's action as to call for some treatment for its relief. This may be found in tapping. A previous puncture with a subcutaneous injecting syringe having been made, and fluid drawn off from the pericardium by its aid, the bulk of the fluid may be withdrawn either by the aspirating needle and syringe, or by free incision (according to the nature of the fluid, whether serous or purulent), in the fourth or fifth intercostal space. In the latter case a drainage-tube should be used, the treatment of the wound being conducted with antiseptic details. See *Paracentesis Pericardii* under PARACENTESIS. The prognosis, however, in such cases is exceedingly grave. Comparatively few cases recover, especially where pus is found in the pericardium. In such cases, post-mortem examination generally reveals more or less old blood-clot still existing in the pericardiac cavity, and a certain amount of adhesion between the surfaces of the heart and pericardium.

H. G. HOWSE.

PERIMETRY.—Besides determining the visual acuity (see VISUAL ACUITY), by which we obtain information as to the state of functional perfection of the macula lutea, it is often necessary to ascertain whether the functions of the whole extent of the retina are normal or not. This examination of the 'field of vision' is sometimes called 'perimetry,' and is most accurately made by the aid of an apparatus called a perimeter.

Abnormalities may exist at any part of the field of vision, which may have merely defects in acuity or exhibit breaches in continuity. The interruptions in continuity may be both regular and irregular. The regular manifest themselves by some limitation of the normal extent in one or more particular or, it may be, in all directions; the irregular breaches are more or less blind portions surrounded by normal, or relatively normal, portions of the field of vision. To these the name of 'scotomata' has been given. To make an accurate examination of the field of vision it is neces-

sary to make use of some sort of perimeter. For rough estimates it is often sufficient for the observer to place himself opposite the patient, who, if it be the right eye that is to be examined, is instructed to fix steadily the observer's left, if the left his right eye. If the observer at the same time maintains a steady fixation of the patient's eye, the respective fields of vision in different directions will correspond, so that any movements of the fingers made by the observer and seen by him above, below, or to either side, should also be seen by the patient. In this way we may rapidly determine if there is any restriction, by simple comparison with a normal standard. One precaution only is necessary in the case, more especially when there is a possibility of slight defects only existing: the examination should be made in a shaded room, with an illumination only just sufficient to cause no restriction in the extent of one's own field.

Various different forms of perimeter are in use. Those who have frequently occasion to make examinations of this nature, naturally prefer one which enables them to effect the examination as rapidly as possible; and for this purpose use is made of a self-registering perimeter, by means of which a chart of the field is pricked off as the examination is being made. A cheap form of perimeter can be made by ruling concentric circles on a black board, the radii of which are determined by multiplying the distance of the eye from the centre of the board by the tangent of 10° , 20° , 30° , 40° , and 50° , a chin-rest being fixed, with a support for the lower margin of the orbit, at a suitable distance from it. To measure the field at a further angular distance from the centre, it is necessary to have a semicircular arm of steel or wood with the degrees marked up to 90° , and capable of revolving round the centre of fixation in a plane parallel with that of the board. In all perimeters there is some arrangement, generally a chin-rest, by which the head is brought into such a position that the eye to be tested occupies the centre of a spherical space, and fixes some object at a distance from it equal to the radius of the spherical surface bounding that space; while the extent of peripheral vision, in any direction and for any particular small object, is given by the angular distance to which that object may be moved away from the point of fixation on the spherical surface. It is obvious that rays from all points on this surface cannot possibly enter the eye—practically indeed, only those from some portion of the half of the surface or hemisphere cut off by a plane

passing through the eye at right angles to the line of fixation. In practice it is found more convenient to use, instead of a complete hollow hemisphere, a quadrant or semicircular arm, which, by rotation round the line of fixation, generates the hemispherical surface, and at any point along which the test object may be brought. This arm is graduated, so that the angular distance of the test object in any position along it can at once be read off, and there is usually a graduated circle as well, which at the same time gives the meridional position of the arm with respect to the eye. The distance of fixation is most conveniently taken at about one foot. On the charts, a series of radiating lines represent the meridional position of the arm, and a system of concentric circles the graduation of the arm itself.

The normal extent of the field is subject to variation at the upper, and slightly also at the inner, parts, owing to individual peculiarities in size and shape of the eyebrows and nose. The physiological limits may be taken to be as follows: upwards, 45° ; upwards and outwards, 50° to 55° ; outwards, 90° (often slightly more); outwards and downwards, 80° to 85° ; downwards, 70° ; downwards and inwards, 60° (variable on account of the nose); inwards, 60° ; inwards and upwards, 55° . The extent of the field upwards, and upwards and outwards, is found to be 5° to 15° greater, when the point of fixation is situated 20° or 30° from the centre of the perimeter in the opposite direction, so that we should not always be right in assuming a contraction in this direction, unless no increased measurement resulted from testing with a lower point of fixation.

The determination of the limits for different colours is a matter of much greater difficulty and uncertainty, as the results are influenced by the hue and shade of the colour used, by the size of the coloured objects, and by the quality and intensity of the light under which the examination is conducted. A precaution, that will be found useful in practice, is to have the test objects differently coloured on either side. In this way we are provided with a check on the accuracy of the patient's statements. The most convenient colour to use is some hue of red, as it is for the reds and greens that pathological defects in the colour-sense almost invariably first manifest themselves. If the test colour chosen be examined carefully at the inner side of the field of vision, it will generally be found to change colour. Before becoming absolutely colourless, it will become yellowish,

brownish, or bluish, according to the hue and shade selected, and it is this tint which may with advantage be used for colouring the opposite side of the test object. When the red-green perception is entirely abolished, the limits may be taken for blue or yellow, the vision for which is longer in disappearing. It is, of course, necessary to exclude the possibility of the more usual form of congenital colour-blindness existing, which we should have reason to suspect if the peripheral boundaries for yellow and blue were not restricted.

But the determination of the limits of the field for quantitative and qualitative stimuli does not exhaust the examination of indirect vision; it is important to ascertain whether or not there is any breach in the continuity of the field. Such interruptions or scotomata are usually divided into positive and negative, according as they give rise or not to a consciousness of the interruption. In the one case there is more or less perception of darkness, in the other an entire absence of any visual impression.

The conditions, in which some alteration or restriction of the field of vision occurs, are optic neuritis and atrophy, the functional forms of amblyopia, retinitis, more especially retinitis pigmentosa, embolism of the central artery and thrombosis of the central vein of the retina, opaque nerve-fibres, glaucoma, detached retina, intra-ocular tumours and foreign bodies, choroiditis and coloboma.

Detached retina.—This defect in the field of vision may occur at any part, and has most frequently a more or less indefinite, ill-defined, and irregular boundary. When caused by a tumour, the defect is usually much more sharply defined than in idiopathic detachment. The freshly detached retina generally retains its functions to some extent, so that it is always advisable to make the examination in subdued light, and, of course, under as nearly as possible identical conditions each time. The boundaries for peripheral colour-vision are narrower than the line separating the detached from the undetached portion of the retina.

Retinitis pigmentosa.—The peculiar features are marked concentric limitation with good central vision. The extreme periphery of the retina does not appear to be subject, in the same degree, to the degeneration which constitutes this disease, and we consequently find that, whilst the function of the greater part of the retina is lost, a zone or belt, or it may be only a small temporal portion, retains a part of its light. The state of peripheral vision is

very markedly dependent on the intensity of light, a fact which is well known in connection with the most prominent symptom of this disease, viz. night-blindness.

Embolism.—A loss of half the field or a sector-shaped defect in it, *limited to one eye*, however, occurs in embolism of one of the principal branches of the central artery of the retina. The defect is generally in the upper or lower half of the field. In embolism of the main artery, a small peripheral portion of the temporal side of the field retains, often, more or less completely its function. See RETINA.

Glaucoma.—In this disease Von Graefe showed that the condition of the field afforded an indication of primary diagnostic importance. The limitation which takes place is usually most marked to the nasal side; frequently, indeed, the field inwards and downwards is destroyed to close up to the point of fixation, when the rest remains as yet but slightly constricted and the vision of the centre tolerably good. If the disease has been acute, the operation of iridectomy is generally followed by widening (sometimes very considerable) of the field. The boundaries of the eccentric colour vision are restricted only to the same relative extent as for black and white. See GLAUCOMA.

Hemianopia.—In uncomplicated cases, there are symmetrical defects in both eyes. When to the same side the hemianopia is homonymous. This is by far the most common form, and may be to the right or left, and partial or complete, that is occupying the whole half of both fields, or only sector-shaped, or even insular, portions thereof. The extent to which the function is destroyed in the defective portions of the field varies also greatly, from complete blindness to hemianopia for colours alone. When the defects are to the temporal side in both fields, or to the nasal side in both fields, the hemianopia is heteronymous.

Optic atrophy.—In progressive atrophy there is invariably a limitation of the field. The limitation often takes place all round (concentric limitation), but in other cases the field in one direction is more restricted than in the rest. The restriction is relatively greater for colours. See OPTIC NERVE.

Scotomata occur either in connection with lesions of the retinal elements or independently of gross anatomical alterations, generally owing to some functional intracranial or cerebral disorder. The first may be of traumatic, inflammatory, or vaso-motor origin or be due to malformation. The cause is generally evident on ophthalmoscopic examination. In diffuse retinitis an

annular or ring-shaped scotoma may often be found, either complete or interrupted at intervals, without any corresponding ophthalmoscopic changes. Large or small insular scotomata, not implicating the centre or extending to the periphery, for which no objective lesion can be detected, are occasionally met with. These are often due to hemicrania, a persistence of the amblyopia which is generally only transitory. Central negative scotomata are met with in a class of cases which are almost always, though not exclusively, of toxic origin. See AMBLYOPIA. The scotoma, which may be so slight as only to be readily demonstrable for colours, takes the form of a horizontal oval, stretching from the portion of the field corresponding to the position of entrance of the optic nerve to slightly beyond the point of fixation.

The examination of the field often affords the most delicate means of ascertaining the course taken by any disease, especially when of intracranial origin. As to the prognosis attaching to the state of the field, it is good if there be no limitation of the peripheral extent, even although there be a considerable scotoma at the centre, if the limitation takes the form of hemianopia in which the portions affected are sharply separated from those in which the function is retained. If, on the other hand, there be limitation of the field without any apparent cause, the probability of subsequent atrophy and blindness is very great. A good deal of prognostic significance attaches to the time which elapses for the production of a defect in the field. Generally speaking, the limitations, which come on suddenly, are not so liable to end in atrophy as those of slow, gradual invasion. G. A. BERRY.

PERINEAL ABSCESS, a collection of pus usually under the deep perineal fascia, occasionally under the fascia or sheath of a corpus cavernosum.

Causes.—In the great majority of cases, the abscess is the result of irritation and ulceration of the urethra behind a stricture; and may immediately arise from suppuration of a follicle or lacuna, due to abscess forming around an ulcer, through which perforation has taken place, and urine in small quantity penetrated into the cellular tissue about the urethra. Sometimes, perineal abscess results from a catheter having lacerated the urethra in its passage; more especially if stricture also exist, when the urine pressed into the wound, excites greater irritation in the wounded part. Inflammation of Cowper's glands, an oc-

casional consequence of gonorrhœa, may excite abscess. Lastly, prostatic abscesses point sometimes in the perineum.

It will be seen that abscesses, arising from the above causes, may be divided into those which are connected with the urethra and those which are not; the former set are the more grave, as they contain decomposed urine, and when the abscess has reached the surface they leave urinary fistulæ.

Beginning in causes of irritation behind the triangular ligament, the matter forms deeply, and is directed forwards along the urethra towards the scrotum, or even further into the sheath of the penis before it reaches the surface. Most commonly, if left to itself, it points near the mesial line just behind the scrotum. Occasionally, the abscess empties itself into the urethra, and such a course, though liable to renewed accumulation and repetition of the evacuation into the urethra, is less serious for the patient.

The *symptoms* of perineal abscess are generally as follow:—A patient, the subject of stricture or of chronic inflammation of the deeper portion of the urethra, feels pain and weight in the perineum, with difficulty of micturition. The stream is smaller than usual, and more force is needed to propel it, the immediate cause of this having been an excess of some kind in wine, sexual indulgence, riding, rowing, tennis, &c. Soon, to the sense of weight in the perineum are added throbbing and symptoms of more or less acute pyrexia, restlessness, thirst, and raised temperature. The perineum may be slightly swollen, tender on pressure; in front of the anus, near the bulbous portion of the urethra, a firm, somewhat egg-shaped, deeply-placed swelling may be felt. Fluctuation is only detected when the abscess has burrowed forwards and by the side of the urethra to the integuments.

The *terminations* of this abscess are various. The matter penetrates in different directions, usually in two or more simultaneously.

In these wanderings it may reach the surface at the perineum or through the scrotum, or by evacuation into the urethra or into the rectum, thus producing fistulæ; which, imperfectly emptied, are continually spreading in fresh directions, so as to tunnel the perineum and scrotum in many *culs-de-sac*. During these alternate accumulations of matter and partial evacuations, the patient is much harassed by pain and fever; and when putrefaction occurs, through mixture of the pus and urine, septic infection, indicated by repeated rigors, great rise and

fall of temperature (ranging in the twenty-four hours from 99°·5 or 100° F. to 103° or 104° F.), is the forerunner of death.

The *diagnosis* of a perineal abscess is formed upon the history of preceding urethral disease or injury, on the presence of difficulty and pain in passing urine, and on the detection of a hard, tender, deeply-seated swelling in the perineum.

The *treatment* is, in the first place, to incise through the mesial line and one inch in front of the anus until the collection of pus is reached; evacuation of the abscess being secured, the treatment of the cause of the abscess, such as stricture, must be undertaken when the constitutional disturbance has subsided. But no loss of time in expecting the abscess to point or open itself on the surface should be allowed. The patient's sufferings are thereby only prolonged and his condition made more critical.

BERKELEY HILL.

PERINEAL BAND.—This is a contrivance, formerly much used in combination with Liston's long splint, to maintain extension in fractures of the femur, or in combination with weight-extension in the treatment of hip-joint disease; in the latter case the band is applied to the perineum on the sound side, and tied to the head of the bed. It consists of a soft but firm band, with a tape attached to each end. The middle of the band is applied to the perineum accurately over the tuber ischii, and the ends are carried, one in front of the groin and the other behind the buttock, to the top of the long splint, where they are tied when sufficient extension has been given to the limb.

The perineal band is objectionable on account of its liability to get soiled, its tendency to excoriate the skin, and the difficulty of keeping it continuously over the tuber ischii. Fortunately, however, we are now able to dispense with it altogether, as a far more efficient counter-extending force can be obtained from the weight of the patient's body, when the foot of the bed is raised; the extension being applied by means of a weight attached to the limb.

BILTON POLLARD.

PERINEAL FISTULA. See URINARY FISTULA.

PERINEAL HERNIA.—The protrusion takes place between the bladder and rectum in the male, and between the vagina and rectum in the female. The tumour is more often to one side of the middle line than directly in that line. The sac either

passes through, or becomes covered by, the levator ani. The contents are usually small intestine, but the bladder has been found in the rupture. The hernia occurs in adults only, and is more frequent in females. It is usually quite readily reduced. The hernia has been inflamed, and has also been strangulated. In the latter condition reduction by taxis has been successful. In no case, apparently, has herniotomy been performed.

FREDERICK TREVES.

PERINEPHRITIC ABSCESS is a common condition, often associated with one or other form of renal disease; indeed, it is a question whether it ever arises independently of the latter. The renal diseases most likely to produce the condition are simple calculous pyelitis, pyonephrosis, or tubercular disease of the kidney. In other words, all the graver forms of suppuration in the organ may give rise to abscess around it by extending outwards until the cortex and capsule are perforated; once the soft, loose, perinephral tissues become inflamed, the process extends more or less rapidly. This suppuration is usually early limited by a plastic deposit at the borderland between the sound and inflamed tissue, so that the abscess is soon distinctly bounded. If this limitation take place close to the kidney, it is often a matter of great difficulty to determine whether the pus lies outside or inside the latter. Fortunately, nowadays, this is not a matter of great importance when the question of treatment alone has to be considered.

In discussing the *symptoms*, it is only necessary to point out the few details in which perinephral abscess differs from pyonephrosis. In the first place, the matter seems to lie nearer to the surface in the loin, as indicated by bulging and fluctuation. With pyonephrosis, the enlargement takes place steadily downwards and inwards towards the umbilicus, and the tumour is sharply defined in this region, while perinephritic abscesses tend to spread backwards and outwards, and are not as distinctly defined to the touch. Urinary symptoms are more frequently absent in extrarenal suppuration than in pyonephrosis; in the former there is very likely to be some amount of inflammation of the psoas muscle, causing flexion of the thigh and pain down the front of the limb. Beyond these the subjective and objective symptoms are identical with those of simple PYONEPHROSIS.

The *treatment* is very simple in uncomplicated cases. It consists in free an-

tiseptic drainage at the point of election behind, as in NEPHROTOMY.

The *prognosis* is good in most cases. After the abscess has been drained thoroughly it soon heals, if it has been opened early, and nothing remains but a little stiffness of the psoas, which soon passes off. But if such a case is allowed to run on untreated, the pus may spread widely across the spine, leading to caries of the latter, or down into the pelvis or front of the thigh, causing much mischief; or it may burst into the cavity of the pleura or peritoneum, or into the intestines. The importance, then, of early diagnosis and free drainage cannot be too much insisted on.

ARTHUR E. BARKER.

PERINEUM, Rupture of the—is a not very uncommon accident occurring during parturition, as the result of too sudden distension of the maternal orifice by the passage of the child's head. The extent of damage inflicted may vary considerably in different cases, the following four degrees of the injury being usually described:—1. Superficial laceration of the fourchette and adjacent portion of the anterior border of the perineum. 2. Rupture of the perineum, not involving the sphincter ani. 3. Rupture extending through the sphincter. 4. Rupture through the sphincter, and involving the recto-vaginal septum. Of these four varieties, the two first constitute what is known as *incomplete* rupture; while the third and fourth illustrate the *complete* form of the injury.

Causation.—*Superficial* lacerations are by no means rare—as an accident liable to occur, to some extent, in the great majority of first labours. The more serious injury of *rupture* of the perineum, incomplete or complete, usually results from one or all of the four following causes complicating delivery:—1. Extreme disproportion between the head of the child and the maternal orifice. 2. Undue rigidity of parts (especially in elderly primiparae). 3. Incautious use of instruments. 4. Prolonged pressure from the child's head, inducing sloughing of the tissues, in tedious and difficult labours.

Symptoms.—*Superficial* lacerations do not, as a rule, give rise to such inconvenience as to render subsequent surgical interference necessary. The *second* variety of *incomplete* rupture, on the other hand, is not unusually followed, in time, by troublesome results consequent upon the loss of support to the vaginal wall, inducing a tendency to prolapse. In the *complete* forms of rupture, the patient's condition is further

aggravated by the resulting loss of proper control over the lower bowel, leading to more or less incontinence of faeces. On inspection in such cases, it will be found that the skin surface of the perineum is replaced by a triangular-shaped projection of cicatrised mucous membrane, of which the base blends with the margin of the patulous anal aperture.

Operative treatment may be either immediate or remote in relation to the occurrence of the injury. Whenever possible, the following plan should be adopted as shortly as may be after the completion of delivery.

Immediate Operation.—The patient lying on her side in the usual obstetric position, the nates should be brought close to the edge of the bed, in order that the extent of the rupture may be fully ascertained, for which purpose a good light is essential. The vagina having been temporarily plugged with a sponge, secured by a string in order to facilitate its subsequent removal, the raw surface of the wound is to be thoroughly cleansed with an antiseptic solution. Two or three sutures are next inserted by means of a curved needle, passed at a sufficient depth to ensure firm consolidation of the ruptured tissues. The wound is then carefully dried with a clean sponge, and the surfaces are brought well into apposition by traction on the sutures, which are finally tied in succession from behind forwards. After removal of the sponge, the vagina should be gently syringed out with a warm antiseptic solution, and this must be repeated every four or six hours, according to the amount of lochial discharge. The urine must be drawn off by catheter three or four times daily. The bowels are to be kept quiet by means of opium until the fourth or fifth day, when four ounces of warm olive oil may be thrown into the rectum, and be followed, in a few hours' time, by an enema of plain water. The sutures can be removed as soon as the bowels have acted.

The *remote operation* for the repair of a ruptured perineum is one of a plastic nature, having for its object the coaptation and subsequent primary union of the freshly denuded surfaces of the fissured part. The difficulties of the procedure required will vary according to the extent of the original rupture, whether incomplete or complete, and will also somewhat depend upon the existence, or not, of any serious prolapse of the vaginal wall. A successful result must further be influenced, not only by the amount of attention paid to

the observance of several important details of the operation, but also very materially by the state of the patient's health at the time of its performance. For this reason it should, as a rule, be postponed until the child has been weaned and the health of the mother is fully restored; all sources of local irritation, such as chronic vaginal discharges, hæmorrhoidal conditions, &c., being attended to before anything is attempted.

The operation, usually, is best undertaken about a week after the cessation of a menstrual period. The patient's bowels having been thoroughly relieved by an effectual purgative on the previous day, the rectum should be further cleared by an enema shortly before she is placed upon the table. After induction of anæsthesia, the nates are brought close to the edge of the table and drawn forcibly apart by the hand of an assistant on either side, who at the same time, maintains the patient's knees in the usual lithotomy position. Before commencing, the operator should well syringe out the vagina with a solution of iodine in water, and insert a sponge. Any hairs are then shaved off the labia, and the parts are carefully cleansed.

The following description of the steps of the operation will suffice for either degree of rupture, no rectal sutures, of course, being required when the sphincter remains intact:—

1. A vertical incision is made on each labium along the line of junction of the skin and mucous membrane, extending from a point corresponding to the termination of the nymphæ down to nearly the level of the anal aperture, where the lateral incisions are next united by a horizontal one, carried across the septum at the junction of the vaginal mucous membrane with that of the rectum.

2. On each side, a triangular flap of mucous membrane is dissected off from without inwards, so as to leave in the middle line a V-shaped portion of mucous membrane, which is next freed, from below upwards, as far as to the level of the upper extremity of the previously denuded lateral surfaces. The apex of this central or vaginal flap should now be held up, by means of forceps, until after the insertion and tying of the deep sutures. In denuding the surfaces, whether with the scalpel or scissors, great care is required to completely remove all trace of mucous membrane. Any bleeding, which is chiefly venous, may, if troublesome, be arrested by the temporary use of pressure-forceps.

3. The rectal sutures are next to be inserted, the number required depending upon the amount of injury sustained by the recto-vaginal septum. The best material for this purpose is fine silkworm-gut, rendered pliable by previous immersion in water. Commencing at the central point of the everted anal margin, the operator passes the needle *from* the rectal aspect to the denuded vaginal surface, and thence directly back again through the mucous membrane of the bowel, of which only the extreme edge should be included, with a view to preventing its inversion. Each stitch should be at once firmly tied, and its ends then cut short before the next one is inserted; the only exception to this rule being in regard to the lowermost one, which it is well to leave untied until after the rest of the operation has been concluded.

4. The introduction of the deep sutures is effected as follows:—A sharp curved needle, set in a handle, is entered on the left side opposite the lower external angle of the denuded surface, at about a quarter of an inch distance from the skin-margin, whence it is directed through the remains of the recto-vaginal septum across the bowel, to finally emerge on the right side at a point corresponding with that of its entry on the left. The eye is now threaded with stout silkworm-gut, which is thus passed through as the needle is withdrawn. If possible, the needle should be kept embedded in the tissues throughout its course, the bowel meanwhile being protected from injury by the operator's finger in the rectum acting as a guide. The number of deep sutures required will vary from three to five, of which the second and third ones are to be passed in the same manner as the first, at successive intervals of half an inch. In the introduction of the two highest sutures, the needle, after traversing the inner aspect of the labium, transfixes the triangular flap of the vaginal mucous membrane (above described) before passing onwards through the right labium, to emerge at a point corresponding with that of its entry on the left side.

In cases complicated by extensive prolapse of the posterior vaginal wall, a wedge-shaped portion may, with advantage, be excised from the centre of the vaginal flap, the edges being afterwards adapted by a series of fine sutures knotted on the vaginal surface, with their ends left long in order to facilitate removal.

5. The vaginal sponge is now removed; the passage is syringed out, and the surface of the wound cleansed by means of a

ream of iced water. The patient's knees are brought together again, and the deep sutures are tied firmly in the order of their section, beginning with the lowest one, care being taken to avoid inversion of the inner edges. Finally, the lowest rectal suture is secured.

The bladder having been emptied by a catheter, a folded napkin is applied to the perineum and retained by a T-bandage. The patient's knees are then fastened together, and she is placed in bed on her side.

A modification of the usual operation, advocated by Mr. Lawson Tait, is based upon the principle of removing no tissue whatever; and, further, of avoiding transsection of the skin-edges in the introduction of the deep sutures.

The procedure consists in splitting the main body of the recto-vaginal septum horizontally, by means of curved, sharp-pointed scissors, along the line of cicatricial tissue in front of the opening in the bowel. This incision serves to define the base of a vaginal flap, of which the sides are next freed by cutting vertically upwards upon the inner aspect of either labium. The deep sutures are then passed in the usual manner, excepting that the point of the needle is both entered and brought out upon the raw surface immediately within the line of skin-margin. No 'rectal' sutures are employed in cases of complete rupture involving the sphincter and septum; the passage of one or more deep sutures across the rent, avoiding transfixion of the immediate margins of the opening, will be found sufficient to ensure its closure. Finally, two or three superficial stitches are introduced anteriorly to limit the vaginal orifice.

After-treatment.—The diet should be light and chiefly farinaceous for the first few days. The parts are to be kept dry, but, at the same time, scrupulously clean by daily washing with a stream of antiseptic solution. The catheter must be used as required; or, if desirable, the patient may be allowed to turn over on her face for the purpose of emptying the bladder, after the first forty-eight hours are over. The bowels should be kept confined by repeated small doses of opium during the first three or four days, after which they may be moved by the injection of warm olive oil, followed by a plain water enema.

Daily evacuation should be subsequently secured by the administration of some mild laxative, as compound liquorice powder in a spoonful doses each night. Mr. Tait

prefers to keep the bowels open from the commencement by the daily use of a small enema. As a rule, the deep sutures can be taken out on the eighth or ninth day, any vaginal sutures being removed at the same time. The rectal stitches may be left undisturbed, provided that their ends have been cut short as directed.

In uncomplicated cases the patient may be allowed to leave her bed at the end of a fortnight. W. A. MEREDITH.

PERIOSTITIS.—Periostitis may be acute or chronic, and of the acute forms there are two very distinct varieties.

SIMPLE ACUTE PERIOSTITIS is very frequently the result of an injury, such as a blow. Syphilis also gives rise to periosteal nodes, which are in some cases quite acute. It may be seen, too, after acute articular rheumatism, typhoid fever, measles, and scarlet fever. In fact, a simple acute periostitis may arise from any cause which reduces a patient below his natural condition of health.

Pathology.—The periosteum becomes vascular, swollen, and in this condition is very readily separated from the bone beneath. This simple form of inflammation generally ends in resolution, and the parts involved return to their normal condition. But it may terminate in suppuration; and, when this is the case, a simple abscess is formed, which has less tendency to burrow far before making its way through the fibrous layer of the periosteum than in the case of the diffuse form of periostitis. Generally, the abscess heals up without any subsequent necrosis, but occasionally the exposed portion of the compact tissue dies, and is removed by exfoliation.

Symptoms.—An acutely tender swelling forms over one of the more superficial bones, such as the tibia. It is found, on examination, to be fixed and connected with the bone, and to be so tender as to admit of very little handling. There is no general enlargement of the bone itself, and the tumour, although connected with the bone, feels as if it were quite upon its surface. The other signs of inflammation, such as heat and redness, are also present, and the pain, which is generally worse at night, may be very troublesome if the part be in a dependent position. Should suppuration take place, the opening formed by nature or the surgeon's art will lead directly down to the bone, when examined by a probe. The temperature will probably be raised several degrees, especially during the first few days, and will be most marked at night.

Treatment.—Leeches, hot fomentations, and a brisk purge will give most relief, and may possibly arrest the progress of the disease. The part should be raised on a pillow, and strict rest enjoined. If syphilis be the cause, notwithstanding the acute symptoms (for as a rule in syphilis the periostitis is subacute or chronic), iodide of potassium alone will obtain, at any rate, temporary relief, and may be looked upon in the early stage as almost a specific. See *Chronic Periostitis*. But in acute periostitis, not dependent on syphilis, iodide of potassium is scarcely so efficacious as in the more chronic forms of this disease. An incision should be made as soon as fluctuation is detected, and may even be made, with considerable benefit, before this event in cases in which the symptoms continue unrelieved. It should be made through the periosteum on to the bone, and antiseptic precautions should, under such circumstances, be adopted to lessen the chances of necrosis.

The constitutional treatment should not be neglected, especially where the disease has followed upon typhoid fever or any other exhausting illness. In such cases the patient will require tonics and a generous diet, but whilst the temperature is raised, fluid nourishment and an effervescing saline draught will probably be more suitable.

ACUTE DIFFUSE PERIOSTITIS OR ACUTE NECROSIS is a much more dangerous disease than the one just considered, and requires the highest surgical knowledge and skill to bring the patient successfully through his illness.

Causes.—It is commonly seen in young and growing boys at or about the age of puberty, the patient being generally rather feeble and ill-nourished. It is very rarely, if ever, seen in those that have reached adult age. Some slight injury appears, sometimes, to be the immediate exciting cause. But this is oftentimes so slight as to have been scarcely noticed, and may even be entirely forgotten. This is all that is definitely known as to the causation of this very curious and interesting affection. It is only fair, however, to say that there are, at the present time, good reasons for believing that the peculiar characters of the disease owe their origin to an infective organism or specific virus, planted no doubt on a suitable soil, but introduced from without. It is beyond the purpose of this article to discuss the interesting points for and against this view of the disease, and the reader must refer to the recent inves-

tigations which have been carried out on animals.

Pathology.—The parts most frequently affected are the tibia and fibula, but any long bone may be the seat of this disease. The flat bones, on the other hand, are very rarely attacked. The inflammation very rapidly terminates in suppuration, and the pus thus formed diffuses itself between the periosteum and the bone over a wide and extensive area. If the inflammation starts in the diaphysis, this stripping of the periosteum stops generally at the epiphysal line. But if it should extend to this line, or start in its neighbourhood, the inflammation may extend into the growing tissue between the shaft and the epiphysis, and then, when the process involves the periosteum from one epiphysis to the other, the whole diaphysis may lie loose in a large abscess-cavity. It is stated that it frequently begins at the epiphysal line, and simultaneously extends down the medullary canal on the inside, and between the periosteum and the bone on the outside. In either case, total necrosis of the whole shaft may be the consequence of this disease. French pathologists assert that total necrosis does not occur without this simultaneous osteomyelitis. The joints, as a rule, escape if the inflammation has begun in the diaphysis, but occasionally the epiphysis itself is involved in conjunction with, or without the shaft, in which case the affected joint may fill with pus, and bring in its train all the dire consequences of suppurative arthritis. Irrespectively of this possibility, pyæmia is especially prone to occur in acute diffuse periostitis. When the periosteum has been stripped from the bone over a considerable area, and incisions are not quickly made, the pus with difficulty makes its way through the fibrous layer of the periosteum; and finally, if still unrelieved, diffuses itself among the muscles, forming oftentimes an enormous abscess before it reaches the surface. There is in such a case no rarefaction of bone as in otitis, but the bone simply dies *en masse*. When this has taken place, and the pus has been evacuated, the periosteum begins to form new bone, and a large ensheathing case is eventually produced, with cloacæ for the escape of pus. The further history of this condition is described under **Necrosis**.

The *symptoms* may ensue immediately after an accident or some slight injury, as has been stated under causation, or there may be an interval of a few days before the onset of acute symptoms. But in either

use this history of an injury, trivial though it may be, is so generally given that it cannot be regarded as a mere coincidence.

Shivering or even a rigor, with a temperature of 102° to 104° Fahr., generally shivers in the attack. Headache, loss of appetite, vomiting, and even diarrhoea may also be present. The local symptoms may at a time be in abeyance, and the patient is thought to be suffering from some acute specific disease, especially as the case will probably be that of a child or youth. In two or three days, the local symptoms manifest themselves by pain and a diffused dematous swelling over one of the long bones, generally the femur, tibia, or humerus.

The *diagnosis* may at the time present some little difficulty—i.e. before the presence of pus can be detected by fluctuation. The question generally arises between such diseases as cellulitis, acute rheumatism, and acute diffuse periostitis. In cellulitis, there has generally been some injury to the teguments by a wound, and the inflammation, starting very soon after the injury, is rapidly spread beyond the next joint; while, in acute diffuse periostitis, the swelling has come on more slowly and been confined to the soft parts covering one bone, and has not passed beyond the neighbouring articulations. In acute rheumatism, on the other hand, the inflammation will be confined to the soft parts near the joint, and on inquiry some other joint will probably be found tender on examination, or to have been so during the illness. Should there still be any doubt as to the presence of deep-seated pus, an exploratory puncture with a narrow-bladed knife can do no harm; and it is a matter of such vital importance to make the necessary incisions as early as possible, this exploratory operation should never be neglected in doubtful cases—to anticipate rather than wait for the formation of pus being the object of every surgeon.

If this is not done, fluctuation becomes distinct in a few days, and on introducing the finger through the openings which are then made, the shaft will be found denuded to a variable extent, according to the severity of the case and the length of time that has elapsed since the pus began to burrow, before making its way through the periosteum. On moving the limb it is possible, at this stage, that indistinct crepitus may be felt between the shaft and the epiphysis. This will not be surprising after what has been said, in a preceding paragraph, on the pathology of the disease.

During all this time the temperature has been high, and the other symptoms of

the febrile condition have continued unchecked, but, as soon as the pus has been evacuated, the temperature generally begins to fall and the patient improves. The temperature may again rise with a fresh collection of pus, indicating possibly the want of a counter-opening or a new area of necrosis. But before this has time to take place, or even in spite of the evacuation of pus, symptoms of pyæmia may supervene, or pneumonia, pleurisy, or pericarditis may bring the case to a fatal termination. If an epiphysis of one of the larger joints, such as the knee, has been primarily involved, and suppurative arthritis has ensued, the dangers of such a calamity have been still further increased. Should the patient avoid all these possible causes of shipwreck, he still has a long and exhausting illness before him, if the entire shaft has become necrosed. The profuse suppuration, in such a case, induces emaciation and exhaustion of the gravest kind, but, where only a portion of the shaft of a long bone has been denuded of its periosteum and has consequently died, the symptoms are proportionately less severe. The steps by which the dead bone is eventually removed are considered under NECROSIS.

There are other less common varieties of this complaint than the one above described. A subacute form is occasionally seen, which is much less dangerous; and a multiple form sometimes occurs, in which several bones are simultaneously attacked. The latter is often rather more of the nature of osteomyelitis, and is especially prone to lead, very early, to a fatal result from septicæmia.

Treatment.—Early and free incisions are here imperatively needed, and can alone save the patient from necrosis of the whole shaft. The finger or probe should be passed into the incisions, to see if more dependent openings can be made than the ones first selected. At the same time—and this is the advantage that the finger has over the probe—the opportunity should be seized to estimate the amount of bone that is already stripped of its periosteum. From time to time free incisions may also be required during the subsequent treatment of the case. Absolute rest upon a good splint is oftentimes a great advantage, and is really necessary in those cases in which the epiphysis or joint is involved. Whether the strictly antiseptic method of Lister should be adopted, in such a case as this, is a matter of choice rather than necessity. Putrefaction and decomposition of the discharges should undoubtedly be prevented. But in

the Listerian treatment of acute diffuse periostitis the dressings have to be frequently changed, or they will quickly putrefy, for sources of putrefaction are already present in the pus before it is evacuated. Personally, the writer prefers, in this particular disease, a more open method of treatment, with frequent injections of an antiseptic solution. The question of amputation of the limb has sometimes to be seriously considered, in cases in which the neighbouring joint has suppurated; and the operation may also occasionally be necessary in feeble patients, who do not rally after the incisions have been freely made, but who seem gradually to get weaker and weaker, and in whom the discharge continues as profuse as before, without any sign of diminution—cases, in fact, in which one thinks there is a poor chance of recovery unless this drain be removed, and that speedily.

If the whole shaft of a long bone has become necrosed and separated from its epiphyses, subperiosteal resection may be employed quite early in the progress of the disease, before new bone has been formed by the periosteum. The patient is thus relieved of a very serious drain upon his constitution; for when this can be successfully accomplished, the amount of pus secreted is very greatly diminished, and the new bone that is formed, after the removal of the old shaft, seems as strong and as sound as when it is left within its periosteal sheath. To facilitate its removal, the dead bone may be divided by a chain saw. Each end can then be easily twisted off from its epiphysis, if it has not already become quite detached. *See SUBPERIOSTEAL RESECTION.*

The removal of sequestra at the ordinary time, when they have become loose and detached within an invaginating sheath of new bone, is discussed under *NECROSIS*. Little need be said about the constitutional treatment of this disease, for it is evident that everything must be done which will assist in supporting the patient through an exhausting and trying illness. Tonics and a stimulating nutritious diet must be given as far as they can be borne. Morphia may also be necessary to allay pain, and soothe the irritable condition into which many of these patients fall.

3. CHRONIC PERIOSTITIS.—Simple uncomplicated chronic periostitis is rare, except in syphilis. It is the custom, however, to call almost all cases of thickening and enlargement of bone periostitis, whereas, undoubtedly, osteitis is generally the primary condition

in these cases, whilst the periosteum is only secondarily involved. Consequently, the reader must look to the article on *OSTITIS* for much that he might possibly expect to find here. Taking, then, the syphilitic forms first, as being by far the most important, we find that syphilitic nodes are due to a more or less chronic inflammatory infiltration of the deep layers of the periosteum. They occur both early and late in the disease. The earliest appear between the second and third month after infection, generally on the superficial bones, and yield very readily to treatment. The later variety do not often appear before the second year, and frequently not till a still more advanced period; but, in exceptionally rapid cases, they may trouble the patient somewhat earlier in the disease than even the second year. They do not yield so readily to treatment, and often lead to a development of new bone on the surface of the old. Occasionally they suppurate, and give rise to a troublesome sinus or ulcer. Dead bone is generally found at the bottom of this sinus, but may take years to separate from the living; such sinuses are therefore very slow in healing. The gumma may affect the periosteum as it does other tissues, and, if unrelieved, softens in the usual way, exposing the bone beneath. The latter is then found to be superficially affected, and often falls into a carious and necrotic condition, leading to those frightful ulcerations of bone which are now rarely seen except in our museum specimens.

There is still another form of chronic periostitis, and that is the osteoplastic variety accompanying osteosclerosis. The periosteum here slowly develops new bone, which may be arranged in layers parallel to the surface or in nodulated masses. When the latter assume a definite size and outline, they are sometimes called osteophytes. The new bone that is laid on parallel to the surface, in chronic osteitis, is at first spongy, with large vessels surrounded by round cells and running at right angles to the surface. Part of this new bone is again absorbed, but in a great measure it undergoes the same sclerotic change that occurs in condensing osteitis, and leaves the shaft so much the larger. It is doubtful whether there are other definite causes besides syphilis for the conditions above described. Localised patches of chronic periosteal thickening are seen both in hereditary syphilis and struma, but they are quite as much osteal as periosteal, like the cases of osteosclerosis above alluded to, except that they are generally rather more limited in extent.

Symptoms.—Pain of a dull aching kind, worse at night and in wet weather, is the principal and most characteristic symptom, the chief complaint which is made being the inability to get to sleep after going to bed. This pain is rarely acute. On examination, a swelling is generally felt on passing the tips of the fingers over the part complained of; this is most likely to be the shin or the superficial parts of one of the long bones, such as the tibia, ulna, or clavicle. The superficial soft tissues are found quite free from inflammation, unless a node has accidentally suppurated or the case be one of gummatous periostitis. Tenderness on pressure will vary greatly in different patients, but it is not often acute, although occasionally the slightest touch seems to cause great pain, even in men who are not otherwise very sensitive. This is, however, more generally seen in the earlier nodes, which have been before mentioned under *Simple Acute Periostitis*.

Treatment.—For the early syphilitic nodes, it is not necessary to discontinue the mercurial treatment that has already been begun. The pain and swelling generally disappear as soon as the patient is fully under the influence of the drug. If this fail, the administration of small doses (gr. v.) of iodide of potassium, for a few days, is almost certain to give immediate relief. But unless mercury is continued, as it is for the other early syphilitic manifestations, over a long period, the nodes are liable to return, whether iodide of potassium be given or not. For the later forms of syphilitic periostitis, including the gummata, even when they are fluctuating, iodide of potassium, in gradually increasing doses from gr. x. to gr. xxx. t.d.s., is generally sufficient to procure a very decided and marked improvement in all the symptoms. Occasionally, the improvement is neither very marked nor very prolonged. Mercury should then be given till the gums are slightly touched. It is not often that this is required, and scarcely ever in the gummatous form of periostitis. But when the disease does not readily yield to iodide of potassium, mercury should most certainly be tried, and most suitably in the form of blue pill gr. v. daily, or, if this be insufficient to make any impression, twice a day. Blisters sometimes give great relief, and should always be employed in conjunction with the above treatment, if there is much pain and tenderness. If, notwithstanding the treatment here prescribed, the symptoms still persist, free division of the periosteum at the most tender spot will some-

times do all that is required and bring the case to a successful termination.

If suppuration takes place, notwithstanding the above treatment by iodide of potassium and mercury, and the skin becomes thin, the abscess should be opened with the fullest antiseptic precautions, so as to avoid, if possible, the occurrence of necrosis.

H. H. CLUTTON.

PERIPROCTITIS.—Inflammation of the tissues surrounding the rectum.—The lower part of the rectum, when at rest, is normally closed by tonic contraction of the circular muscular fibres, by which the mucous membrane is thrown into longitudinal, closely approximated folds. During defæcation the tube is more or less considerably distended. In constipated or flatulent subjects, the distension may be very great and permanent from accumulated fæces or flatus. To admit of this variation in calibre, the bowel is surrounded by lax cellular tissue, which below becomes continuous with the adipose tissue of the ischio-rectal fossæ. This cellular tissue contains a large quantity of adenoid tissue, partly diffused and partly aggregated in nodules resembling the solitary glands of the intestine.

This tissue is not infrequently inflamed, and the inflammation may be acute or chronic. It may occur spontaneously, probably from irritation of the adenoid tissue in phthisical patients, or from direct violence, as from blows or kicks, or even from exposure to cold. It may also be due to perforation of the rectum by ulceration or by foreign bodies, as enema-tubes, rectal bougies, fish-bones, &c.; or it may be secondary to inflammation of adjacent parts, as of the prostate, bladder, vagina, or from necrosis of the sacrum or coccyx. If fæcal matter escape from the bowel into this tissue, the inflammation is very severe and extensive.

In the *acute* stage, the patient complains of a sensation of heat and weight in the perineum, and of pain in defæcation. If the inflamed part be small and at some distance from the surface, there may be no external evidence; but if neglected, the inflammation will rapidly spread, and a hard brawny swelling will be found occupying one or both ischio-rectal fossæ. The chronic form is very insidious, and, if due to inflammation of adjacent parts, may fail to attract attention. If neglected, it may result in considerable denudation of the bowel.

When the patient complains of pain in defæcation, without any external sign of the cause, the rectum should be carefully ex-

plored with the finger; and if any part of the mucous membrane be discovered to be swollen, tender, and hotter than the rest, the left forefinger being retained in the bowel as a guide, a straight knife should be introduced alongside the bowel from the anal portion of the perineum, and pushed steadily onwards to a level with the tip of the guiding finger. If suppuration has already commenced, as is usually the case, the exit afforded for the pus will give relief and probably prevent perforation of the bowel. If there be no pus, the bleeding from the inflamed part will prove serviceable. Any more superficial suppuration must be incised in the usual manner, and the cavity washed out with carbolised water. The pus is usually extremely ill-smelling, even when there is no direct communication with the bowel. The wound may be dressed with iodoform and filled with cotton wool. If a rectal fistula result, it must be treated according to the condition of the part.

In *chronic* cases, any retained pus must be evacuated and the wound dressed in a similar manner. Sinuses must be either laid open or irrigated, according to their extent and direction. The exciting cause must also be treated as the requirements of the case may suggest. The patient must be kept at rest in the horizontal position, and an easy daily action of the bowels ensured by suitable diet and purgatives.

JEREMIAH MCCARTHY.

PERITONITIS, or inflammation of the serous membrane that lines the abdomen and covers the contained viscera, is, like inflammation of other tissues, brought about by various agencies, of which the effect is to lessen the vitality of the parts assailed, and to lead to more or less manifest changes in structure and function.

The *causes* of peritonitis are: (1) Bruises, and the resulting irritation; (2) wounds of the abdominal wall and organs, with infiltration of fæces, urine, or other irritating material; (3) ulceration or gangrene of the intestine, with the like infiltration of injurious material; (4) the distributed infective particles of pyæmic, tubercular, and malignant disease. The varieties of peritonitis are, accordingly—(a) simple, (b) septic, and (c) specific, while in extent it may be 'partial' or 'general,' and in degree 'chronic' or 'acute.'

Anatomical Changes and Mechanism.—In the event of bruise, the peritoneum may be the seat of ecchymosis in varying degrees, punctiform or diffuse, as may be seen on post-mortem examination after early death

associated with fractured pelvis, ruptured viscera, &c. A slight amount of what is virtually simple peritonitis may attend the infliction of a bruise, and is present in wounds of the peritoneum which heal by a perfectly aseptic process. But, under both conditions, the recovery of the patient is so simple and speedy that the evidence of peritonitis is not conspicuous, and, in the event of death from other cause, its anatomical traces may be confined to an inconsiderable adhesion or superficial scar—provided that the parts be kept at rest. Undue intestinal movement, brought about by the use of food improper in such circumstances, may, however, aggravate the simple peritonitis to the exudation of extra lymph and its resulting adventitious adhesions. Permanent traces of previous peritonitis occur in the form of fibrous tissue variously attached to the serous surface, as smooth bluish-white opacities, streaky cicatrices, close adhesions, delicate fibrous shreds, or firm cords and bands. In extent, the above forms of simple peritonitis are 'partial.' In chronic (simple) peritonitis associated with ascites, the surface of the membrane may be slightly injected and thinly coated with granulations, lymph, or both, in the absence of pus, decomposition, and constitutional infection. In extent, chronic peritonitis is 'general.'

In the event of extensive putridity, as on the decomposition of blood or serum after operation, or on the flooding of the serous sac with the juices of the alimentary canal through sudden perforation of intestine, the result is a rapidly fatal septicæmia, chiefly characterised before death by collapse, with sometimes an entire absence of inflammatory phenomena. Petechiæ on the peritoneum and other serous membranes are not uncommonly found after death in septicæmia, and are not to be confounded with those of ecchymosis. Between these extremes are found average cases of 'acute peritonitis,' which may be 'partial' or 'general,' according to the extent to which the serous surfaces are implicated, and in which the inflammation is not infrequently partial at first, and subsequently spreads until more generalised, or until 'universal.'

Acute peritonitis is always septic, and occurs under circumstances of wound, ulceration, gangrene, and pyæmic or other metastatic infection. In perforating wound of the peritoneal cavity, decomposition may arise from without; in wound of the intestine, by issue of fæces from within; in ulceration, by leakage of fæces; in gan-

green, by imbibition through the putrefying issues; and in pyæmic abscess at the surface of the liver, the source of peritoneal irritation is evident. The anatomical changes denoting acute peritonitis are exudation of lymph, pus, or both, and vascular injection, which are as apparent after death as during life. The amount of lymph exuded may be no more than a stippled film, or may be enough to be stripped off with the fingers; while its colour may be yellow, straw, brown, or green. The pus exuded may have any consistence between that of milk and that of clotted cream, with any of the above colours. Either exudation may exist singly, or the two may be combined in any proportion. The vascular injection may vary from the scantiest redness to a crimson or purple velvety fulness on the parietal or visceral surface, like the condition of the eye called 'pannus.'

In the specific peritonitis of tubercle, the exudation is found, as the name implies, in dotted nodules, which vary from the size of hardly visible grains to that of mustard-seeds, green, yellow, white, or opalescent, often on a pink ground of vascular injection, at various distances apart, or forming a continuous granular membrane.

In various forms of malignant disease, the peritoneal membrane is found to be dotted in varying extent and profusion with scattered nodules of tumour-growth, averaging a size between those of mustard-seeds and peas, but in some instances forming considerable masses. Their colour is often simply white; but pink, red, or purple tints may be imparted by a varying blood-supply; while an additional or alternative yellow stain may be present through general jaundice or local bile-staining. The anatomical resemblances between tubercular and malignant infiltration of the peritoneum are sufficiently great to render their distinction in some cases difficult, without regard to other circumstances. To the latter condition the term 'malignant peritonitis' is sometimes applied.

The symptoms of peritonitis are local and constitutional. The local consist of pain, tenderness, and the impairment of visceral muscular functions. The constitutional are alterations in the temperature, pulse, and respiration, and also in the demeanour and facial expression. There is lastly the act of vomiting, a symptom probably indicative of local irritation and of constitutional sympathy combined.

The pain and tenderness in cases of bruise are great at first, and may be aggravated if the parts concerned be not

kept at rest. In cases of perforation of the bowel and flooding of the peritoneum with faecal fluids the pain is great, as if from the pungent irritation of the noxious matters, and ceases only in advanced collapse. In acute peritonitis, more slowly brought about by similarly septic means, the pain and tenderness are conspicuous, the area of the latter being proportioned to the 'partial' or 'general' extent of the affection. In tubercular and malignant infiltration the pain may be, and commonly is, *nil*.

The temperature in peritonitis may be raised or lowered. The painful state of mere bruising may be attended with elevation of temperature, apparently due to the pain; while the onset of the same condition may be ushered in with a lowered temperature and a certain amount of shock. In acute—that is, in septic—peritonitis the temperature is also commonly elevated a few degrees at first, followed in later stages by depression. Local changes may have something to do with this, as in the case of bruising, but the major part of the change, whether elevation or the reverse, is probably due to septic absorption, for exactly similar elevations and depressions of temperature are well known in cases of septic poisoning not arising in the abdomen. The pulse is characterised by greatly increased rapidity and hardness, which in the acute form of peritonitis is almost 'wiry' to the finger.

The respiration in peritonitis is sometimes quickened and shallow, owing to pain and tenderness affecting the respiratory muscular efforts, especially when the peritonitis is diaphragmatic. Part of this may be due to a febrile state and quickened pulse when they exist.

In peritonitis of all kinds, there is a tendency to impairment or irregularity of the intestinal muscular functions. This may be accompanied by flatulent distension, or may follow a state of contraction, both of which conditions may be found in different portions of the same bowel. In consequence of impaired intestinal functions, whether strictly localised or affecting a considerable length of the gut, constipation may result, and is commonly recognised as a frequent attendant symptom. But, also actual obstruction of intestine, sub-acute and even acute, may directly result from acute peritonitis, and its symptoms may be those which alone attract attention.

Vomiting occurs in cases of severe abdominal contusion and concussion, but does not commonly persist. In acute peritonitis vomiting generally occurs, and per-

sists while food or drink is administered, on the early avoidance of which it is mitigated, while it can be totally allayed by the subcutaneous administration of morphia. In tubercular and malignant peritonitis vomiting is not regularly present, and may be totally absent.

The *diagnosis* of acute traumatic peritonitis is based upon the presence of pain, tenderness, abdominal distension, and vomiting, following an injury. In that due to perforation of the intestine or vermiform appendix, with slight or gradual leakage, the same typical symptoms exist; but the suggestive circumstance of the injury is not present, and thus an important diagnostic aid is wanting. In either, the symptoms referring to peritoneal injury may be masked by those due to blood-poisoning, and attempts at diagnosis may fail, or may even reveal only those of intestinal obstruction, until post-mortem inspection clears up the obscurity of past events. Cases of perforation of the appendix, in which the leakage is not intraperitoneal, may result in abscess, iliac or lumbar, with or without subsequent fecal fistula; and may, in cases of still less severity, cause symptoms identical with those of typhlitis and perityphlitis. In cases of bruise the conspicuous local pains, together with the circumstance of injury, render a recognition of peritonitis not difficult, even though the symptoms are not immediately apparent; while in tubercular and malignant peritonitis there are often—in fact, usually—no symptoms by which even a clue can be gained, except in the event of ulceration, when by fecal contact acute peritonitis may be set up, with the symptoms above related. See PERTYPHLITIC ABSCESS.

The *treatment* of peritonitis is simple enough, whatever be its cause. The local symptoms to be combated are pain, tenderness, and the tendency to flatulent distension. The pain and tenderness can be counteracted by opiates and by alcohol; speedy relief being obtained in a state of urgency by morphia subcutaneously given. Any of its salts act well if pure, the hydrochlorate and acetate being quite satisfactory when fresh, but liable to decomposition after long keeping. The sulphate seems to retain its purity longer than any other salt of morphia, and is consequently to be preferred, in doses, for an adult, of from a quarter to half a grain in the first instance. After even frequent repetition, it is hardly likely that more than half a grain will be required, while for a first dose, urgently needed, less than a quarter of a grain can

seldom be relied upon for this purpose. In the absence of urgency, the same drug may be confidently given, and found satisfactory, by the mouth, in doses varying from an eighth to a quarter of a grain, repeated every four, six, eight, twelve, or twenty-four hours. Under the same circumstances laudanum or liquor opii sedativus, in doses of ten to sixty minims, may be equally relied on. A dose of wine or spirit and water, administered by preference hot, may be given occasionally to supplement, or even in mild cases instead of, the opiate. For children, the same medication by the mouth, in doses appropriate to their age, on the scale of a drop of laudanum for each year of life, cautiously increased or repeated if relief be not speedy, will generally suffice.

The diet should at the same time be entirely liquid, and confined to small quantities of beef-tea, soups, or water-arrowroot suitably sweetened and flavoured with alcohol. Meat and fish should be rigorously avoided, except in the preparation of broth, which should be carefully strained; milk should be equally strictly interdicted until the symptoms are checked; and even bread should not be given pending improvement. At first, in fact, and during the existence of severe symptoms of any kind, it is better to avoid nourishment altogether, and to put off its administration until temporary ease is obtained, and even until craving hunger on the patient's part demands it. Warm tea, barley water, toast water, and the like, may at most times, however, be judiciously given to relieve thirst. When the pain is gone, and has shown no tendency to return, bread or toast may be broken into the tea and broth, and this kind of diet should be continued until a stool passes. In even a mild case, properly managed, much time is saved by omitting the food at first; while, in cases of more severity, a rigid attention to diet is essential, and will often result in a spontaneous easy stool in the first or second week after a previous obstinate constipation. But during recovery, moderate flatulence, without special pain or tenderness, may exist with constipation and scybala, especially if the diet have not been scrupulously attended to, and will then yield to a well-timed simple enema of hot water. It should be distinctly understood, however, that such interference is not justifiable during the existence of symptoms indicating any degree or stage of the original affection, and is only permissible during the period of actual convalescence.

The application of fomentations, poultices, or dry heat, to the abdomen is found

to be acceptable in many cases of peritonitis. The alternative abstraction of heat by laying on an ice-bag or a wet cloth (preferably in a single layer) is productive of exquisite comfort in other cases.

The above treatment may be uniformly adopted in all forms of peritonitis, and is no less successful than essential in severe remediable cases. The mildest instances are always the better for it, though no doubt susceptible sometimes of spontaneous recovery, while septic cases generally prove fatal in spite of all treatment. Even in fatal cases, however, some of the symptoms are combated by the treatment, and the sufferings of the patient minimised.

RUSHTON PARKER.

PERITYPHLITIC ABSCESS.—A localised collection of pus formed in connection with the cæcum or its appendix, situated either within or without the peritoneal cavity. By some authors the term is limited to abscesses commencing in the loose areolar tissue behind the cæcum. Taking the broader significance of the term, we must separate perityphlitic abscesses into intra- and extra-peritoneal. These forms differ from each other sufficiently to justify a separate description, though clinically it is often difficult, and sometimes impossible, to distinguish one from the other.

EXTRA-PERITONEAL PERITYPHLITIC ABSCESS.—*Anatomy.*—The loose tissue behind the cæcum is a part of the general subperitoneal areolar tissue. It is continuous above with the fat about the kidney, and internally with the loose tissue surrounding the iliac vessels and with the pelvic cellular tissue. A collection of pus, forming immediately behind the cæcum, can readily extend upwards to the kidney, inwards to the brim of the pelvis, and forward to the groin above Poupart's ligament. It is prevented from reaching the thigh by the attachment of the fascia iliaca and fascia transversalis to Poupart's ligament. Should it extend inwards to the pelvic cellular tissue, it may escape from the pelvis with the gluteal or sciatic artery through the great sciatic notch, and thus appear in the buttock, but it is shut off from the perineum by the recto-vesical fascia. It is possible for the pus to make its way to the surface along the spermatic cord or through the femoral ring, but such a course is extremely rare. In the majority of cases it comes forward, and appears above the outer part of Poupart's ligament. When the abscess is very acute it may perforate the iliac fascia, and thus come in direct contact with the ilio-psoas muscle, and it

may then extend upwards towards the spine, and downwards to the thigh, taking the course of an ordinary psoas abscess. This is, however, a rare occurrence. Abscesses arising in connection with the kidney, or in the pelvic cellular tissue, can easily extend in the subperitoneal fat to the neighbourhood of the cæcum, and may thus appear to have commenced in that region.

Causes.—An extra-peritoneal perityphlitic abscess most commonly arises as a complication of disease of the cæcum, with or without perforation of the gut. When not a consequence of perforation, it probably commences in the lymphatic glands which lie behind the cæcum. The diseases which give rise to it are—simple typhlitis from faecal accumulation; and ulceration from tubercle, typhoid fever, dysentery, or stricture of the great intestine at some point lower down. Cancer of the cæcum may lead to perforation in its later stages. Perforation of the vermiform appendix near its root may also be a cause of an extra-peritoneal abscess. In some cases, the appendix is placed completely behind the cæcum, and an abscess resulting from any disease of it would then be situated behind the gut. Perforation of the cæcum at any part covered by peritoneum very rarely causes a localised collection of pus, as it is usually speedily fatal from diffuse peritonitis. In some exceptional cases the abscess may arise without any recognisable cause.

Symptoms.—The special symptoms of a perityphlitic abscess are preceded by those of the disease to which it is secondary. It would be out of place here to describe the symptoms of typhoid, dysenteric, or tubercular ulceration of the cæcum, and those of stricture of the great intestine and of cancer of the cæcum are fully treated of under **INTESTINAL OBSTRUCTION**.

The symptoms of simple typhlitis are pain and tenderness in the region of the cæcum, with swelling taking the form of the distended gut. At first the pain is dull and aching, and the tenderness is not usually very acute, but by the second or third day, if the attack does not subside, the symptoms become more severe. It not uncommonly happens that the exacerbation takes place somewhat suddenly, so as almost to suggest that perforation of the gut has taken place, but the absence of collapse and of the signs of diffuse peritonitis is sufficient to show that this is not the case. The sudden increase in the severity of the symptoms is believed to be due to an extension of the inflammation to the peritoneum covering the cæcum. When this has taken place, the tenderness

is such that no accurate examination by manipulation is possible without the administration of an anæsthetic. In order to relieve tension the patient lies with his right thigh flexed. Nausea and vomiting are common symptoms at this stage. The bowels are usually confined throughout the attack, and most commonly the patient has suffered for some time from habitual constipation. It occasionally happens, however, that, even in cases of very considerable fecal accumulation in the cæcum, a channel may exist through the mass, allowing of the passage of a daily motion. The temperature, which is normal at the beginning of the attack, usually becomes slightly elevated during the period of acute tenderness. Under proper treatment by rest, hot fomentations, and small doses of opium, the symptoms gradually subside in about a week from the commencement of the attack; some hardened feces are passed, either naturally or by the help of enemata, and the patient recovers. In most cases he remains liable to similar attacks throughout life.

The extra-peritoneal perityphlitic abscesses must, for the description of their special symptoms, be divided into two classes—those that do not communicate with the gut, and those that do.

In the abscesses not communicating with the gut, the pain and tenderness which have attended the previous typhlitis, instead of subsiding, become more acute, and the swelling becomes more distinctly localised in the outer and lower part of the iliac fossa, in the neighbourhood of the anterior superior spinous process, and the outer end of Poupart's ligament. The temperature rises to 103° Fahr. or more, with evening exacerbations. There may possibly be a rigor, but this is not common. Accurate examination is scarcely possible without an anæsthetic, but, when the muscles are relaxed, a firm elastic swelling fixed in the iliac fossa can easily be recognised. Fluctuation may be difficult to detect, owing to the depth at which the fluid is placed. On observing the movements of the abdominal wall during respiration, it will be noticed that they cease at a point some distance above Poupart's ligament, instead of reaching to the groin as in health. At this stage of the disease, recovery may take place by the abscess discharging itself into the cæcum, but this can only occur if the tissues round the abscess are sufficiently consolidated to prevent fecal extravasation, and if the opening is sufficiently free to drain the cavity. Under

other conditions, the communication with the gut only aggravates the disease and hastens the advance of the abscess. Should the abscess continue to advance without this complication, the swelling increases, redness and œdema appear above the outer end of Poupart's ligament, and fluctuation becomes distinct. In the great majority of cases the abscess remains limited to the iliac fossa, extension upwards towards the kidney, or inwards towards the pelvis, being very rare. Perforation of the iliac fascia and extension downwards to the thigh are also extremely rare.

If the abscess from the beginning communicates with the gut, or if it continues to extend as a consequence of imperfect drainage after opening into the cæcum, the progress of the disease is usually more acute. The temperature is higher, the constitutional disturbance greater, and rigors are not uncommon. In fact, the contents of the cavity now being necessarily very foul, symptoms of septicæmia or pyæmia may appear before the pus reaches the surface. Extensive burrowing, either upwards and inwards, or downwards upon the thigh after perforation of the fasciæ, is also far more common than in the non-perforating abscess. The chief local symptom of communication with the gut is the presence of gurgling or crepitation on manipulation, and tympanitic resonance on percussion over the swelling in the iliac fossa.

Both forms of abscess, if unrelieved by treatment, usually perforate the abdominal muscles near the anterior iliac spine. They then expand over the iliac region beneath the deep layer of the superficial fascia of the abdomen. Thus, an apparently superficial abscess, on being opened, may be found to communicate by a narrow neck with a large cavity in the iliac fossa. Less frequently, the pus burrows between two of the muscles entering into the abdominal wall. Finally, the abscess will burst, discharging extremely offensive pus. If there is no communication with the gut, the offensive odour is merely due to the close contiguity of the fluid with the bowel, and soon disappears. If the gut is perforated, fecal matter is mixed with the discharge, and, as the cavity contracts, a fecal fistula or artificial anus may remain, according to the size of the opening.

Diagnosis.—An extra-peritoneal perityphlitic abscess has to be distinguished from—(a) an ordinary iliac or psoas abscess connected with disease of the bones of the pelvis or the vertebræ; (b) an acute abscess following a strain or other injury of the

psoas or iliacus; (c) a perinephritic abscess extending downwards; (d) an abscess following pelvic cellulitis, extending upwards and outwards into the iliac fossa. The diagnosis is often extremely difficult. If the abscess is chronic, and is accompanied by considerable signs of irritation of the psoas, and if it extends down to the thigh beneath Poupart's ligament, it is probably connected with the bones. An acute abscess, early passing under Poupart's ligament, would also have probably commenced beneath the iliac fascia. A perinephritic abscess, by the time it reaches the iliac fossa, would probably cause distinct fulness in the lumbar region, and would, in the great majority of cases, be accompanied by pus in the urine. Pelvic cellulitis occurs almost exclusively in women, and is recognised by a vaginal examination. Still, as a true perityphlitic abscess may extend upwards to the kidney and inwards to the pelvis, and may, moreover, perforate the fasciæ and extend to the thigh, it is evident that the diagnosis must be, in many cases, very difficult. Even the presence of gas in the cavity is not proof that the abscess is truly perityphlitic, as both perinephritic abscesses and those arising in pelvic cellulitis have been known to perforate the intestine. The diagnosis must, in many cases, depend very much upon the previous history, and even here it is not always easy to distinguish between attacks of typhlitis and of renal colic.

Pathology.—The post-mortem appearances present nothing peculiar. The interior of the abscess is frequently foul and the walls sloughing.

Treatment.—The prevention of suppuration in typhlitis belongs rather to the physician than the surgeon. It is sufficient to state here that rest, hot fomentations, restricted diet, and moderate doses of opium form the essential features of the treatment. Purgatives and enemata are calculated to increase the danger of suppuration. When there is reason to believe that suppuration has taken place, if the symptoms are not very acute, the same treatment may be continued for a short time in the hope that the abscess may discharge itself by the bowel. As soon as the swelling becomes superficial, and the hope of spontaneous cure is past, an opening should be made. This should not be delayed after it is evident that the abscess is advancing towards the surface. Should any doubt exist as to the presence of pus, the swelling must be explored with the aspirator, but in such cases aspiration is seldom sufficient to cure the disease. If

the symptoms are not very acute, it may, however, be tried once or even twice before making an opening. If the pus is very offensive, or if it contains faecal matter, it is better to open at once. The opening should be made by an incision close to the anterior spine, if possible. The skin and fascia and the external oblique only need be divided with the knife, the deeper parts being opened up with a pair of polypus-forceps. A large drainage-tube should then be inserted, and some form of antiseptic dressing applied. Should fæces escape with the pus, little can be done, beyond drainage and cleanliness, to avoid the formation of an artificial anus or faecal fistula. Should these form, their treatment is most unsatisfactory. The opening in the bowel being at the posterior part of the cæcum, it is impossible to reach it, and the gut is too firmly fixed by adhesions for it to be possible to perform the operation of enterectomy, as has been done for artificial anus in other situations.

INTRA-PERITONEAL PERITYPHLITIC ABSCESS is, almost invariably, the result of perforation of the vermiform appendix. Should any disease lead to perforation of the cæcum in the part covered by peritoneum, rapid death from general peritonitis almost always results.

Perforation of the vermiform appendix is most commonly caused by the presence of a concretion or foreign body within it. According to Dr. Fenwick, who has collected and analysed 129 published cases, amongst those in which the nature of the obstructing body is recorded, 28 were concretions, 14 hardened fæces, and 5 foreign bodies. Amongst the cases in which no concretion was found, tubercular ulceration seems to have been the most common cause of perforation, and a few occurred during or after typhoid fever. Concretions are most common in males under twenty years of age.

The effects produced by perforation of the vermiform appendix will vary with the anatomical relations of the part and the situation of the ulceration. According to Mr. F. Treves, the appendix commonly lies behind the end of the ileum and its mesentery, and is directed upwards and towards the left. In the only other common position it ascends vertically behind the cæcum. It may, however, be so placed that its free end lies at the brim of the pelvis. If perforation takes place near the attached end, or if the whole tube lies behind the cæcum, the abscess would be in the same situation as that resulting from disease of the cæcum,

and would be indistinguishable from it. When the appendix occupies its more common situation, and when the perforation occurs in the free part, it is followed either by general peritonitis, usually fatal under a week, or by the formation of a collection of pus enclosed in a cavity, formed by the surrounding coils of intestine firmly united to each other by adhesions. According to Dr. S. Fenwick, in 95 cases of which accurate details could be obtained, 38 presented localised collections of pus.

Symptoms.—Premonitory symptoms may be entirely wanting, but occasionally there is a history of obscure pains in the right iliac fossa, or of periodic attacks indistinguishable from ordinary typhlitis.

When the abscess forms behind the cæcum, the symptoms are those already described of extra-peritoneal perityphlitic abscess.

In the cases in which the perforation is followed by diffuse peritonitis, there is usually a sudden invasion, often during some violent exertion. The pain commences in the right iliac fossa, but soon extends to the whole abdomen. There is constipation, distension of the abdomen, and absence of evident movement of the intestine. The abdomen is tender, but most markedly in the right iliac fossa, where some fulness may be felt. The symptoms are much less severe than those of perforation of the stomach or other parts of the intestine, as the extension of the inflammation is less rapid, owing to the absence of the abundant extravasation of the intestinal contents. For the same reason collapse is not marked. Vomiting, often of dark-coloured matter, is a marked symptom, as in all other forms of peritonitis.

The symptoms of perforation with localised peritonitis are much more obscure. The invasion is usually somewhat sudden. There are localised pain and tenderness in the right iliac fossa. The pain resembles colic in character. There is usually constipation, but it may alternate with diarrhoea. Vomiting is commonly present. After a day or two, an irregular, diffused elastic swelling may be felt in the right iliac region. It is most commonly situated rather higher up and more internal than the swelling formed by an extra-peritoneal abscess. At this time rigors are not uncommon, and the temperature may reach 108° to 104° F. If unrelieved by treatment the swelling increases, and most commonly after a time, perhaps extending into the third week, the symptoms of general peritonitis supervene and the patient dies. At

no time, as a rule, can fluctuation be felt in the swelling, owing to its deep situation and the difficulty of fixing it. Should the abscess lie nearer the pelvis than usual, there may be irritability of the bladder, and sometimes a firm mass can be felt from the rectum, composed of the adherent coils of intestine round the abscess. Cases have been recorded in which recovery took place by the abscess discharging itself into the bowel, but such a fortunate issue is so rare that it cannot be taken into consideration. Almost every case, if not relieved by operation, will die.

Pathology.—At the post-mortem examination, general peritonitis with purulent fluid in the peritoneal cavity is the most marked feature. The amount of fluid varies considerably, but is often not very great. The intestines are intensely injected, and adherent to each other by soft adhesions. In the localised form, a cavity is found containing pus, the walls being formed of the surrounding intestines glued together by firm adhesions.

Diagnosis.—In the diffuse form, the diagnosis from other forms of perforative peritonitis can only be made by the comparative absence of collapse, by the commencement of the pain in the right iliac fossa, by the tenderness in that region, and by the somewhat gradual extension of the inflammation to the peritoneum generally. The localised form most closely resembles simple typhlitis, and sometimes can hardly be distinguished with certainty. As a rule, the swelling is more diffused and more acutely tender at an early period than in simple typhlitis, and the constitutional symptoms are much more marked.

Treatment.—Until recently, patients suffering from perforation of the vermiform appendix were practically left to die under the soothing influence of opium, when their end was not hastened by purgatives, enemata, and other violent measures. There is, however, no doubt that whenever perforation takes place, the only chance of life lies in opening the abdomen early, and freely draining the cavity. This is applicable to those cases in which there is general peritonitis, and still more so to those in which the mischief is localised, whenever a diagnosis can be made.

The incision should, as a rule, be made above the outer part of Poupart's ligament, and should be about three inches in length. The muscles should be carefully divided and the peritoneum freely opened. The vermiform appendix should then be sought for, and, if it be found and is evidently

diseased, it may be ligatured with catgut and cut away. If there is diffused peritonitis, with purulent fluid amongst the coils of intestine, an attempt may be made to clean the cavity by means of sponges, squeezed as dry as possible after being soaked in some antiseptic solution, such as carbolic acid (1 in 40), corrosive sublimate (1 in 500), or tincture of iodine (f3ij. to Oj.). If the pus is distinctly localised in a cavity, it is better not to attempt to clean it out, for fear of breaking down the surrounding adhesions. After the operation a large drainage-tube should be inserted, and the wound closed as far as possible by sutures. The operation should be performed with antiseptic precautions, and some antiseptic dressing be applied afterwards.

It may be necessary, in some cases, to modify the incision. Should the swelling be situated nearer the middle line, the abdomen might be opened at the outer border of the rectus, but care must then be taken not to wound the epigastric artery. The middle line can seldom be a suitable situation for the incision, as, being so far removed from the seat of the disease, the drainage would not be efficient.

This operation has been performed in a considerable number of cases with very encouraging results. MARCUS BECK.

PES GIGAS (*Synon.* Macropodia).—This affection is that form of congenital hypertrophy which is limited to part of one extremity, usually the foot, though occasionally the tissues of the leg as well are affected.

Two varieties are met with—(a) *symmetrical* or *true*, in which the whole foot or limb is colossal, all its parts being developed to an equally gigantic degree; (β) *unsymmetrical* or *false*, in which only portions of the foot are altered, either by large fatty excrescences, or by one or two gigantic toes, or by both conditions together. The tissues chiefly affected are the integumentary and the bony. Then there is great increase of the fatty subcutaneous tissue, which often takes the shape of pads or lumps; coexisting with these, capillary nævi, often of large extent, may be met with; other angiomas are more rare. The arteries do not seem liable to change, the veins are often varicose and thickened, the lymphatic vessels dilated, whilst the glands are unaffected.

Where colossal toes are present, the phalanges and metatarsal bones are enlarged and greatly elongated, but all parts of the enlarged bones are usually in proportion. With regard to the muscles and tendons going to the enlarged toes, the

former are not usually over-developed, the latter are much elongated. In some cases, a confused matting together of the muscles in the sole has been observed. The ligaments are much thickened, and secondary articular distortion is not infrequent. The affection never interferes with birth. The causes are quite unknown.

Treatment.—Pressure is always to be tried as early as possible and persisted in, by means of strapping, elastic stockings, or Martin's bandage. If pressure be made judiciously and perseveringly, steady diminution in the size of the foot or limb may confidently be expected. But it must be remembered that pressure, however used, must not be applied too tightly in young subjects, especially where a nævoid condition of the skin is present, otherwise ulceration, hæmorrhage, and a low form of erysipelas are only too probable.

Ligature of the main artery has been suggested, but, judging from the varying results which have followed upon its adoption for elephantiasis, this step is not to be recommended, save in cases where persevering pressure has failed, or where the congenital hypertrophy is accompanied by unusual pulsation in, or undoubted increase in the size of, the arteries, or by large angiomas not yielding to other means.

In cases of symmetrical or true hypertrophy, amputation will not be required if pressure is made use of early and persevered with. Before proceeding so far, the surgeon will do well to bear in mind that 'an unnaturally heavy and cumbrous limb is after all as good as a wooden leg' (Holmes).

In cases of unsymmetrical hypertrophy, amputation of any large toes should be resorted to early. If this enlargement coexist with localised overgrowths of fat, so as to render the foot cumbrous and the wearing of boots difficult, removal of a portion or all of the foot should be resorted to.

W. H. A. JACOBSON.

PHAGEDÆNA.—This term is applied to a disease which occasionally occurs in hospitals in this country, and also in private houses, and which by some is designated as 'hospital gangrene.' It differs essentially, however, from this disease, both in the slighter ravages which it produces, and also in the fact that it may originate quite independently of any hospital contamination or influence.

Causes.—There can be no doubt that in many cases this disease is distinctly syphilitic in its origin; but there can be as little doubt that it may occur quite independently

of this cause. During the year 1863 a severe epidemic of this disease occurred in St. George's Hospital, no less a number than ninety-two cases occurring. Many of those attacked were quite young children, or individuals in whom there could not arise the slightest suspicion of syphilis, and it seems impossible to believe that the whole of these ninety-two patients could have been the subjects of that malady. It is, no doubt, possible that this disease may be generated by dirt and overcrowding, and therefore owe its origin, in some cases, to defect in hospital management, and want of proper hygienic precautions; but, nevertheless, the facts elicited in the above-mentioned outbreak prove that it cannot always be attributed to this cause. For, of the ninety-two patients suffering during this outbreak, in only nineteen did the disease break out in the wards, the remaining seventy-three occurring out of the hospital, some of them never having been near the building until they were brought suffering from the phagedæna.

Symptoms.—The disease presents itself in two forms: in the one there is the formation of black sloughs; in the other the wound spreads by a sort of ulcerative process, and without the formation of distinct sloughs. In the former case, the wound becomes dry and loses its healthy appearance, the surrounding parts become swollen and tense, and of a bright red colour, but speedily become darker, the wound being covered with a black slough. This extends, the inflamed tissue falling into a condition of gangrene. After a time, however, the progress is arrested, a line of demarcation forms, and the slough slowly separates in the form of greyish-black viscid masses.

In the other variety, there is no formation of a slough, but a rapid liquefying or melting away of the parts. The surface of the sore assumes a greyish appearance, and becomes covered with a semi-gelatinous fluid. The edges gradually melt away into this material, and there is no swelling, cedema, or redness of surrounding tissues.

Treatment.—In considering the treatment of this affection, a distinction must be made between those cases which owe their origin to a syphilitic cause and those which do not. In the former nothing but mercury appears to have any influence in checking the progress of the disease, and the best plan of administering it is by means of local calomel fumigation. The fumes of calomel (from 15 to 20 grs.), applied locally to the sore once or twice a day, rarely

fail to arrest the sloughing in a surprisingly short space of time. The non-syphilitic form requires a different plan of treatment. Here, the free administration of opium, and a liberal diet, with a judicious supply of stimulants, the sore being at the same time covered with a charcoal poultice, rarely fail to arrest the disease. Some surgeons recommend the free application of fuming nitric acid to the part, but the treatment appears to be unnecessarily severe, causes very considerable pain, and does not—at all events, in every instance—succeed in arresting the sloughing. The local irrigation of the wound with a solution of carbolic acid or sulphurous acid has succeeded, in the writer's hands, in checking the gangrene when other means have failed. Mr. Hutchinson has recommended, in these cases, the treatment by a warm bath. The patient is placed in a bath at a temperature of about 96° to 98° F., and is kept there for eight consecutive hours. This is repeated daily until the gangrene is arrested. While in the bath, care is taken to maintain the water at the same temperature. Those who have tried this plan speak warmly of its success.

PHANTOM TUMOURS. See ABDOMINAL TUMOURS, Diagnosis of.

PHARYNGEAL STENOSIS.—*Definition.*—A constriction or narrowing of some portion of the pharynx, due to cicatricial contractions following ulceration.

Cause.—Generally syphilitic, occasionally strumous, and, more rarely, simple ulceration.

Pathology.—The constriction may be met with in three situations—first, between the naso- and mid-pharynx; secondly, between the mouth and pharynx; thirdly, in the lower pharynx about the level of the hyoid bone. Stenosis occurring at the junction of the pharynx with the œsophagus will be found described under *Strictures*. See *ŒSOPHAGUS, Injuries and Diseases of the*.

I. In the first situation, the stenosis is produced by the adhesion of the soft palate to the posterior wall of the pharynx, into contact with which it has been drawn by the contraction of cicatrices following ulceration about the posterior pillars of the fauces. In this way the upper part of the pharynx may be completely cut off from the rest of that cavity, and from the mouth; but usually a small aperture is left between them about the situation of the uvula, which is itself generally destroyed by the ulceration.

II. The constriction between the mouth and the pharynx is due to the soft palate being drawn downwards towards the base of the tongue, through contractions and adhesions following ulceration about the anterior pillars of the fauces. Here the stenosis is never complete, although the aperture left for the passage of food, &c., between the soft palate and base of the tongue may be exceedingly small.

III. Stenosis in the lower pharynx is the result of an extensive ulceration of the pharyngeal walls about the level of the hyoid bone, the subsequent contraction of the cicatrices drawing in the tissues concentrically, so that the pharynx assumes in this situation an hour-glass shape. The stricture is situated above the opening of the larynx, and the aperture left has to serve for the passage of both food and air. Complete stenosis, therefore, is incompatible with life; but the writer has seen the pharynx so constricted at this spot that it would barely allow the passage of a crow-quill.

Symptoms.—When the stenosis is between the naso- and mid-pharynx, beyond some alteration in the voice but little inconvenience is usually experienced. When between the mouth and pharynx, in addition to some alteration of the voice, there will be more or less difficulty in swallowing according to the extent of the contraction. In stenosis of the lower pharynx, there is increasing difficulty in swallowing, with attacks of cough and dyspnoea on exertion. Soft food only can be swallowed, and this but slowly and in small quantities at a time, while paroxysms of suffocative dyspnoea occur if a larger morsel than usual is attempted to be taken.

Diagnosis.—In the first and second situations the stenosis is evident on inspection; and in the third it is readily made out by the laryngoscope.

Treatment.—Stenosis between the upper and mid-pharynx seems to be beyond the reach of treatment. Were the aperture enlarged it would rapidly re-contract, and, could it be kept open, would only cause the patient greater inconvenience by allowing the regurgitation of food, &c., through the nose. When swallowing is seriously impeded by a constriction between the mouth and pharynx, the tissues may be divided in an upward direction either by the knife or galvano-cautery, and re-contraction prevented by the daily passage of a bougie. But, if little inconvenience is felt, the stricture is better let

alone. Stenosis of the lower pharynx, when at all extreme, calls imperatively for treatment, as life is endangered from the liability of a portion of food to block up the narrowed passage. With the aid of the laryngoscope, the cicatricial tissue should be divided in the middle line in a backward direction, by a guarded knife or the galvano-cautery. The writer has found a Ricord's urethrotome admirable for the purpose. Further dilatation may subsequently be obtained, and re-contraction prevented by the daily passage of bougies of increasing sizes. Tracheotomy as a preliminary had better be done, since the manipulation sets up very severe paroxysms of cough and dyspnoea, and, during division of the tissues, death has followed from blood escaping into the trachea.

W. J. WALSHAM.

PHARYNGOTOMY. See ŒSOPHAGOTOMY.

PHARYNX, Diseases of the.—PHARYNGITIS, or inflammation of the pharynx, although it sometimes occurs alone, is generally associated with more or less inflammation of the palate and fauces, and has a tendency to spread to the larynx and nasal passages. The inflammation is commonly of the catarrhal variety (*acute and chronic catarrhal pharyngitis*); but it may fall chiefly upon the glands of the pharynx (*granular or follicular pharyngitis*), or more rarely may spread deeply and end in diffuse suppuration (*phlegmonous or suppurative pharyngitis*). Sometimes it is attended with deficient secretion and atrophy of the mucous membrane (*pharyngitis sicca*), and occasionally it assumes an erysipelatous character (*erysipelatous pharyngitis*), and is then generally associated with erysipelas of the face.

(a) *Acute Catarrhal Pharyngitis*, or common sore-throat, is generally the result of exposure to cold. It is attended with more or less fever and malaise, and usually terminates spontaneously in a few days. The familiar symptoms of soreness or pain in swallowing, hoarseness, and perhaps slight deafness, and the local redness and swelling vary according to the intensity and extent of the inflammation. Confinement to the house, and an aperient followed by a simple saline mixture and an astringent gargle, are all that is generally required in the way of treatment.

(b) *Chronic Catarrhal Pharyngitis*, or 'relaxed sore-throat,' may follow on repeated attacks of the acute, or be induced by gastric disturbance, the abuse of alcohol,

tobacco, &c. It is characterised by a sense of dryness of the parts, especially in the morning, by a constant desire to moisten or clear the throat, and, if the uvula is elongated, by a tickling cough. The mucous membrane is slightly red and swollen, and frequently covered with tenacious mucus, and the uvula is often relaxed and elongated.

Treatment.—The exciting causes must be carefully avoided, the bowels regulated, and the health improved by tonics. Locally, an astringent gargle or lozenges may first be tried; but, if the affection be obstinate or of long standing, local remedies, to be effectual, must be applied either by the brush or in the form of sprays. Amongst the remedies that may be thus used with advantage are chloride of zinc (gr. x.—xx. to fʒj.) or tannin dissolved in ether, applied with the brush; and sprays of chloride of ammonium, bicarbonate of sodium, alum, &c. (gr. v.—xxx. to fʒj.). When the uvula is much elongated, its extremity should be removed.

(c) *Granular or Follicular Pharyngitis*, also known as ‘clergyman’s sore-throat,’ is a chronic inflammation of the mucous follicles of the pharynx, and is not infrequently associated with a similar condition of the mucous follicles of the naso-pharynx, posterior nares, entrance of the larynx, and upper part of the oesophagus.

Causes.—A debilitated, and especially a strumous constitution, appears to predispose to the affection; whilst long-continued over-exertion of the voice, exposure to cold, and the breathing of air charged with irritating particles or fumes are amongst the chief exciting causes. Hence the affection, though met with in others, is most common in those engaged in public speaking, as clergymen, auctioneers, &c., and in photographers, employed in chemical works, &c.

Pathology.—The constant contact of cold or vitiated air renders the mucous membrane dry, and stimulates the follicles to over-secretion. The extra work thus thrown upon the follicles leads to catarrhal proliferation of their epithelium, blocking of their orifices, retention of secretion, and general hypertrophy of the tissues of which they are composed. In some cases, the hypertrophy prevails and the secretion rapidly diminishes; in others, the secretion continues excessive, and the follicles become distended and exude a viscid mucus or even a caseous material, whilst very little hypertrophy ensues. Hence, the disease has been divided into the hypertrophic and exudative varieties. In the hypertrophic form it would appear, from the observations

of Stoerk, that isolated proliferations of the general epithelial covering of the pharynx also occur.

Symptoms.—A sense of dryness in the throat, hoarseness, loss of power over the voice, a continual hawking and desire to swallow for the purpose of clearing the throat, and a tickling, dry, harsh, or painful cough, are commonly complained of in the early stages of the disease. Later on, these symptoms become more pronounced, and complete loss of the voice, pain and difficulty in swallowing, impairment of hearing, and even permanent deafness and loss of the sense of smell may supervene, as the disease spreads to the surrounding parts. The pharynx presents somewhat different appearances, according as the disease assumes the hypertrophic or exudative form. In the former, the hypertrophied follicles and epithelial elevations give the posterior wall of the pharynx a characteristic granular appearance. The granules are at first scattered and isolated, of a lenticular shape, and of a deeper colour than the rest of the mucous membrane; but subsequently they coalesce, forming flattened masses or ridges. In the exudative form, the follicles appear distended with secretion, and a viscid mucus can often be seen adhering to them. The mucous membrane between the granules may be either hypertrophied or atrophied, and is generally traversed by large and tortuous veins.

Treatment.—The general health must be improved by attention to the secretions, by tonics, and change of air, all exertion of the voice being forbidden, and every known source of irritation avoided. Locally, the granulations must be severally destroyed by the galvano-cautery wire, the actual cautery, or the solid nitrate of silver fused on the end of a silver probe. Two or three of the granulations only should be destroyed at a sitting, which, as a rule, should be made not oftener than twice or three times a week. Between the application of these remedies, the parts may be painted with solutions of chloride of zinc, or sprayed with weak astringent lotions of alum, tannin, and the like. To allay the irritation sometimes caused by the destruction of the follicles, lozenges containing opium, chloride of ammonium, or bromide of potassium, or inhalations of steam may be prescribed.

(d) *Phlegmonous or Suppurative Pharyngitis* may occur spontaneously, or follow an injury of the pharynx. The inflammation spreads deeply and widely; the submucous tissue, and even the constrictor

muscles, become infiltrated with inflammatory products; and suppuration frequently ensues. The pus may track down the course of the pharynx and oesophagus, or make its way forward into the tissues of the neck, compressing the upper air-passages and obstructing the entrance of the larynx.

The *symptoms*, at first those of ordinary sore-throat, rapidly become alarming. Swallowing becomes difficult or impossible, respiration laboured, the pulse rapid, and the tongue furred and brown. The pharynx is intensely red and swollen, the neck often puffy and cedematous, and death usually follows, in three or four days, from sudden spasm of the glottis.

Treatment.—The strength must be supported by fluid nourishment and stimulants. Brand's extract, strong beef-tea, and the brandy-and-egg mixture, should be given in frequently repeated doses, or administered by the rectum if the patient is unable to swallow. The atmosphere should be kept moist and steam occasionally inhaled, and sulphate of quinine (gr. v.) taken every three or four hours. Preparations for instant tracheotomy should be made, and the operation performed as soon as it becomes evident that life is in danger from spasm of the glottis. Should suppuration occur in any accessible situation, an incision, to allow free exit to the pus, should be made.

(e) *Pharyngitis Sicca*, or atrophic pharyngitis, appears to be the result of repeated attacks of catarrh. The mucous membrane is thin, dry, and glazed, the normal secretion is completely absent, and the veins are varicose. The symptoms are those of soreness and dryness of the throat, in speaking and swallowing. The disease admits only of palliative treatment. For this purpose cubebs, given both locally and internally, inhalations of steam, tincture of benzoin, and the like, will be found useful.

ULCERATION.—Ulceration, when it attacks the pharynx, is seldom limited to that cavity, but, like inflammation, more often affects at the same time the soft palate, fauces, and tonsils; whilst not infrequently the base of the tongue, the epiglottis, and sometimes the larynx and nasal cavities also become involved in the process. Ulceration of the pharynx may occur in the course of syphilis, struma, and tuberculosis, on the breaking down of epitheliomatous and other growths, on the bursting of herpetic vesicles, and in connection with ulceration of the tonsils in the affections known as simple and malignant ulcerative sore-throat.

(a) *Syphilitic Ulceration* may be divided into the superficial and deep. Superficial ulceration may occur both in the earlier and later stages of syphilis. In the earlier stages it is generally due to the erosion of syphilitic mucous patches, then so common about the fauces, palate, and tonsils. The ulcers are generally symmetrically arranged, quite superficial, sharply defined, covered with a grey mucopurulent discharge, and surrounded by a slight areola of redness. In the later stages, superficial ulceration often assumes a serpiginous form, and extends widely over the pillars of the fauces and palate. Deep ulceration is nearly always due to the breaking down of gummata, and only occurs in the later stages of syphilis. The ulcers are circumscribed, their edges sharp-cut, slightly overhanging, and surrounded with an areola of a characteristic coppery red colour, and their base is covered with a yellow purulent discharge, mixed with shreds and *débris* of breaking-down tissue. The ulceration is sometimes limited to the posterior wall of the pharynx, but generally attacks simultaneously the soft palate, tonsils, fauces, and base of the tongue, and frequently the larynx and nasal cavities. It often extends deeply, leading to caries or necrosis of the adjacent bones; while the subsequent cicatrization may lead to various forms of occlusion and stricture of the pharynx. See PHARYNGEAL STENOSIS.

Treatment.—For the ulcerations occurring in the earlier stages, small doses of mercury should be given internally, while the throat may be gargled with 'black-wash,' or painted with a solution of nitrate of silver, chromic acid (gr. x. to f 3j.), or boroglyceride. For the later ulcerations, large doses of iodide of potassium (gr. x., xv., or even gr. xxx. three times a day), combined with decoction of cinchona or quinine, should be given internally; whilst the parts should be cleansed with gargles of chlorate of potash, carbolic acid, or chlorinated soda, and then dusted with iodoform, or painted with a strong solution of nitrate of silver.

(b) *Strumous Ulceration*.—Many pathologists do not admit the existence of strumous ulceration in the pharynx, the variety here described as such being regarded by them as the result of congenital syphilis, modified by the strumous constitution of the patient. This form of ulceration is most frequently met with in badly nourished and strumous children, especially of the poorer classes. Generally

beginning in the soft palate, it gradually spreads to the fauces and back of the pharynx, and sometimes to the hard palate and nasal cavities, slowly but persistently destroying the parts and often producing great deformity; more rarely it begins in the posterior wall of the pharynx. The ulceration is generally sharply defined, though the mucous membrane around may be slightly thickened; the edges of the ulcer are raised and everted, not sharp-cut as in syphilis, nor surrounded by the coppery red zone so characteristic of the latter affection. The base is covered by a ropy, greyish, muco-purulent discharge, through which here and there granulations are seen projecting, giving it a mottled, pinkish appearance.

Treatment.—Cod-liver oil, combined with syrup of iodide of iron, or the compound syrup of phosphate of iron in drachm doses, with unstimulating diet and residence at the sea-side, are the constitutional measures attended with the best success. Locally, the parts should be well cleansed with a weak carbolic lotion, and then dusted with iodoform, or cauterised with nitrate of silver fused on the end of a probe. If there is any suspicion of a syphilitic taint, anti-syphilitic remedies should be combined with local treatment.

TUBERCLE.—Deposits of miliary tubercles are occasionally met with in the pharynx, as one of the local manifestations of acute general tuberculosis. In the earlier stages, the tubercles appear as scattered or confluent patches of grey granulations on the sides and posterior wall of the pharynx, often also on the palate and roof of the mouth. They differ from syphilitic mucous patches, for which they have been mistaken, in the absence of the inflammatory zone of redness, and in their more translucent appearance. Later, they break down, leaving small lenticular ulcers with slightly overhanging and hyperæmic edges and a caseous-looking base, while fresh crops of miliary tubercle are deposited around. The symptoms are those of acute pulmonary consumption, with local soreness of the throat, and the patient usually succumbs to the lung-affection in a few months.

HERPES.—An eruption of herpes, similar to that which occurs on the skin, is occasionally met with in the pharynx. The affection appears to be of neurotic origin, and is most prevalent in damp and cold climates. It usually runs an acute course of a week or ten days, and is attended with more or less smarting pain, soreness

of the throat, and fever. The eruption is mostly limited to one side, and is more common on the fauces and soft palate than on the posterior wall of the pharynx, while a similar eruption is often present upon the lips and corners of the mouth at the same time. The vesicles either disappear in a few days, leaving no trace, or they break down into small superficial ulcers, which in some cases become covered with a false membrane. When several such ulcers become confluent, the membrane covering them may be mistaken for that of diphtheria; but the presence of a few scattered ulcers as yet uncovered by membrane, and of similarly shaped, isolated patches of the membrane itself, and the absence of any tendency of the disease to spread, are points which will usually serve to distinguish herpes. An aperient, followed by small doses of quinine and the use of a simple gargle, is all that is generally required by way of treatment.

W. J. WALSHAM.

PHARYNX, Extirpation of the.—This operation has within the last few years been performed in some instances for the removal of growths which, from their situation in the lower pharynx, have been hitherto considered beyond the reach of surgery. The following is the method devised by Langenbeck:—Tracheotomy is first performed, and the trachea plugged with Trendelenburg's tampon-cannula. The head being well drawn back and the face turned to the opposite side, an incision beginning just below the lower jaw, midway between the symphysis and the angle, is carried over the greater cornu of the hyoid bone in the direction of the sternohyoid to just above the tracheal wound. The integuments, platysma, and omohyoid are divided, and the posterior belly of the digastric and stylo-hyoid muscles detached from the hyoid bone. The superior thyroid, lingual, and facial arteries and veins, and the superior laryngeal nerve and its external branch are next divided. The pharynx is then opened, and the larynx drawn firmly to the opposite side, and rotated so that its posterior surface is well exposed. The front and side walls of the pharynx are now detached from their connections, and the posterior wall is divided transversely on a level with the lower border of the soft palate, and separated from the vertebral column. The pharynx, with the growth, is then finally removed by severing it from the œsophagus. A tube should be placed in the œsophagus

or the purpose of feeding the patient, and the tampon-cannula retained in the trachea for some days, to further guard the air-passages from the entrance of food, saliva, and the secretions from the wound.

W. J. WALSHAM.

PHARYNX, Injuries of the.—These may be classified under—(1) Incised, lacerated, punctured, and gunshot wounds, inflicted either from within, through the mouth, or from without, through the neck; (2) burns and scalds, due to the sudden passage of flame, as in a gas explosion, swallowing boiling water or inhaling steam; and (3) charring or other chemical lesion of the mucous membrane from drinking strong acids or caustic alkalies.

(1) *Wounds* are not uncommonly inflicted from within, by the patient falling whilst holding a sharp-pointed body, as a pipe-stem or stick, in the mouth; by the forcible extraction of a sharp-angled body, as a false-tooth plate which has been impacted in the lower pharynx, by the incautious use of probangs, &c. Wounds from without are usually inflicted with a suicidal or homicidal intent. In these the pharynx is generally wounded in front, between the hyoid bone and thyroid cartilage (*see* THROAT, Injuries of the). Wounds of the pharynx, particularly the punctured variety, may be attended by fatal hæmorrhage, consequent upon a large vessel being penetrated or subsequently opened by ulceration of its walls. They are not infrequently followed by acute cellulitis, due to the escape of food into the tissues of the neck, or to the instrument with which the wound was inflicted being broken off short and remaining as a foreign body. Circumscribed collections of pus may also result from like causes. *See* RETRO-PHARYNGEAL ABSCESS.

(2) *Scalds* of the pharynx are most frequent in young children, from inhaling steam or drinking hot water from the spout of a tea-kettle. They should always be regarded as grave, from their liability to be followed by cedematous laryngitis.

(3) *Lesions* of the mucous membrane, caused by swallowing corrosive liquids, are generally of secondary import to the graver injuries which are usually simultaneously inflicted upon the stomach, larynx, or œsophagus. *See* ACIDS, ALKALIES, Swallowing

the arrest of hæmorrhage. Any bleeding vessel that can be seized should at once be tied. In punctured wounds about the fauces, inflicted from within the mouth, the bleeding vessel may be invisible, or if seen it may be impossible to ligature it. In such a case attempts should be made to twist it, or if this fails the forceps may be left on. If the source of the hæmorrhage cannot be discovered, and is not very severe, the patient should be given ice to suck, an ice-bag may be placed on the side of the neck, or solid perchloride of iron applied to the wound, or pressure made upon it by means of a stick wrapped round with lint. These means failing, or the hæmorrhage threatening life, the common carotid, as a last resource, must be tied. Where a foreign body, as a portion of a pipe-stem, is found in the wound, it should not be removed till the common carotid has been compressed and preparations have been made to tie it if required, as a fatal gush of hæmorrhage has been known to follow its extraction. When the wound is so situated that food is liable to escape into the tissues of the neck, the patient should be fed by the rectum for the first few days. Should suppuration occur, an early outlet for the pus must be made. *See* RETRO-PHARYNGEAL ABSCESS.

In burns and scalds of the pharynx, and in injuries from swallowing corrosive liquids, &c., the patient should be carefully watched for signs of cedematous laryngitis, and everything should be in readiness for tracheotomy. Milk diet should be prescribed, or nutrient enemata if the patient is unable to swallow. *See* SCALD OF THE GLOTTIS.

FOREIGN BODIES IN THE PHARYNX.—Fish bones, pieces of meat, false-tooth plates, and coins are the foreign bodies that have most frequently been found in the pharynx. The situation at which they are most liable to become impacted is opposite the cricoid cartilage, where the pharynx narrows to join the œsophagus; but they may also become lodged between the tongue and epiglottis, and, in the case of fish-bones or pins, in the tonsils or between the pillars of the fauces. Bodies like the latter, moreover, may be impacted lengthways across any part of the cavity.

Symptoms.—These necessarily vary according to the nature and situation of the foreign body and the length of time that it has been impacted. A small sharp-pointed body, as a fish-bone, may cause a pricking sensation in the parts and some distress or pain in deglutition, symptoms which, owing to the scratching of the mucous membrane,

Treatment.—For the treatment of suicidal and gunshot wounds of the pharynx, *see* THROAT, Injuries of the, and GUNSHOT WOUNDS of the Neck. In wounds of the pharynx, attention should first be given to

may continue after the bone has been dissolved or swallowed. Large bodies, as a false-tooth plate, may cause great pain on swallowing, or render the act altogether impossible, or may produce severe paroxysms of cough and dyspnoea from reflex spasm of the glottis, or from direct pressure upon the larynx; while a large mass of food may cause fatal suffocation by blocking up the pharyngeal opening of the larynx. Though cases are on record where foreign bodies have remained in the pharynx for a long time without causing much irritation, their continued presence has usually led to ulceration, perforation and fatal hæmorrhage, peri-oesophageal abscess, or œdematous laryngitis.

Diagnosis.—A careful inspection, aided by the laryngoscope and finger, will usually detect a foreign body if lodged about the fauces, base of the tongue, or region of the cricoid cartilage. When beyond the reach of the finger, its detection may be difficult. Nothing may be felt externally, and it may be only after a long and patient examination by pharyngeal forceps, œsophageal bougies, coin-catchers, &c., with the patient under chloroform, that its presence and situation is at last discovered.

Treatment.—If a portion of meat or other substance is obstructing respiration, the finger should at once be plunged into the throat and attempts made to dislodge it. If these fail and suffocation is imminent, instant laryngotomy should be performed. A fish-bone, pin, or false-tooth plate, when within reach of the finger, may often be hooked out with the nail, or, if seen, be readily extracted with the dressing-forceps. When the foreign body is too low down to be felt by the finger, its extraction, especially in the case of a false-tooth plate, may tax the ingenuity of the surgeon. The patient had better be put under chloroform, and attempts made to grasp the plate with pharyngeal forceps having blades opening in different directions. By passing these closed, and using them as a sound, the plate may be struck and a fair estimate formed of its position. Considerable force may have to be used in its removal, as the hooks, by which the plate is attached to the teeth, often become embedded in the tissues. When the forceps fail, attempts should be made to snare the foreign body with one of the various forms of coin-catchers, or to sweep it out in front of the bristles of the expanding horsehair extractor. Whilst passing these instruments beyond the foreign body, care must be taken not to force it lower down the passage. Sometimes an emetic,

or, where this could not be swallowed, one-sixth of a grain of apomorphia injected subcutaneously, has succeeded. This treatment, however, is not unattended with danger, and should only be employed under exceptional circumstances. If attempts at extraction fail, three courses are open: to remove the foreign body by the operation of *ŒSOPHAGOTOMY*; to try and push it down into the stomach; or to allow it to remain, in the hope that it may become loosened by ulceration. The first plan of treatment is, in the writer's opinion, the right one to pursue.

W. J. WALSHAM.

PHARYNX, Tumours of the.—New-growths in the upper part of the pharynx, and at the junction of its lowest part with the œsophagus, are treated of in separate articles. See *NASO-PHARYNGEAL GROWTHS*; *ŒSOPHAGUS, Injuries and Diseases of the*. Nearly all varieties of tumour have been observed in the pharynx; all are rare in this situation, but the fibrous, the fibro-myxomatous, the fatty, the epitheliomatous, and the sarcomatous are perhaps the least so. Pharyngeal growths may be pedunculated or sessile, and may spring from the back or lateral walls of the pharynx, the soft palate, the base of the tongue, and the region of the epiglottis and aryteno-epiglottidean folds. They may have their origin in the mucous membrane or submucous tissue, in the fibrous covering of the vertebræ, or in the bodies of the vertebræ or intervertebral cartilages, and in the glands by the side of the pharynx. When arising behind the pharynx, they are sometimes spoken of as post- or retro-pharyngeal tumours.

Symptoms.—The tumours often attain a considerable size before the surgeon is consulted, the patient's attention being first called to them by difficulty in swallowing, obstructed breathing in certain attitudes, from the growth either pressing upon or partially occluding the opening into the larynx, or, when the growth is high up, by some alteration in speech. When arising behind the posterior wall, they push the mucous membrane before them, and appear as smooth, globular, uniform projections in the cavity of the pharynx. They may be hard and resistant, or soft and fluctuating, and fixed or movable, according to their origin and attachments. A rapidly growing sarcoma or other soft solid tumour may greatly resemble a retro-pharyngeal abscess, and the diagnosis can often only be made by puncture with a grooved needle. See *RETRO-PHARYNGEAL ABSCESS*. A new-growth in the lateral wall may be simulated by an

aneurism of one of the carotids. Care only is required, however, to make the diagnosis.

Treatment.—Small and pedunculated growths may be readily removed either by ligature of the pedicle and excision, or by the cold wire or galvanic *écraseur*. Before deciding upon the removal of sessile and larger growths, a careful investigation of their attachments and connections should be made, both by the finger and laryngoscopic mirror, as these may be such—especially when the growth involves the lateral wall—as to preclude the possibility of its extirpation with a reasonable chance of the patient surviving the operation. The retro-pharyngeal growths, when unattached to the vertebræ and of moderate size, may often be shelled out with ease by the finger, after a vertical incision has been made through the mucous membrane covering them. In attacking a growth of large size, where there is a probability of much hæmorrhage, preliminary tracheotomy should be performed, and the tracheal wound plugged with Trendelenburg's tampon-canula, to prevent the escape of blood into the air-passages. For malignant growths involving the aryteno-epiglottidean folds, the removal of the larynx will probably be necessary. This question is fully discussed under LARYNX, Growths in the. Recently, Langenbeck has extirpated the whole pharynx or malignant growths beyond reach by the mouth.

W. J. WALSHAM.

PHIMOSIS is a malformation of the prepuce which prevents its being retracted behind the glans penis. It is either congenital or acquired. In congenital cases, the prepuce is abnormally long, and sometimes so contracted at its orifice that it is impossible either to expose the glans penis or to effect retraction without much difficulty and pain. The skin is abundant, but the mucous membrane is shorter than usual, and the narrowing which prevents the retraction is always found at the junction of the skin and mucous membrane. Congenital phimosis is a fertile source of irritation and disease. Even when the prepuce is simply elongated, and not sufficiently contracted at its orifice to prevent its withdrawal from the glans, it still favours the retention of the secretions beneath it, which may result in balanitis. But, short of this, there can be no doubt that an elongated prepuce is frequently the cause of much local irritation, leading to the habit of masturbation. When, however, the orifice of the prepuce is so narrow as to prevent retraction, the results are of a much more

serious nature. One of the most common symptoms is nocturnal incontinence of urine, which frequently resists all attempts at cure short of circumcision.

Occasionally the long, contracted prepuce acts as an impediment to the passage of the urine, and gives rise to symptoms resembling those of stone in the bladder. In very extreme cases of this sort, the prepuce becomes enormously distended by the retention of the urine beneath it, requiring the pressure of the hand to extrude it through the orifice. The severe straining to void the urine under these circumstances is a frequent cause of hernia in young children, and it is also stated that hydrocele and phimosis are often associated. The effect of this deformity on the nervous system has been noticed by Professor Sayre of New York, who states that paralysis of the lower extremities is often a direct result of the irritation caused by congenital phimosis. Erichsen also states that he has seen cases of chorea arising from the same cause. In after-life the evils of phimosis are not abated. There is no doubt that the immunity from chancreous affections, known to exist amongst the Jews, is due to the rite of circumcision, and it is inferred, from the statistics collected by Jonathan Hutchinson, that a long prepuce renders its possessor more liable to the infection of syphilis. At any rate, it makes the treatment of venereal disease more difficult, and in some cases impossible without recourse to an operation.

Congenital phimosis is sometimes a complete bar to sexual intercourse, or even when connexion has been effected, conception is prevented owing to the retention of the seminal fluid beneath the foreskin. It has been asserted, without much foundation, that this malformation predisposes to cancer of the penis.

Acquired phimosis is the result of inflammatory deposits in the prepuce, caused generally by balanitis, chancre, or repeated attacks of herpes preputialis. When it results from a balanitis the swelling is simply oedematous, accompanied by a profuse purulent discharge from the orifice of the prepuce. If, however, it is due to indurated chancre, a point can generally be felt beneath the prepuce more painful and indurated than the surrounding tissue. See **BALANITIS**. In advanced life, the preputial orifice will be found sometimes contracted from repeated attacks of herpes, especially in gouty subjects.

The *treatment* of phimosis, whether congenital or acquired, generally requires surgical interference. In congenital phimosis,

there can be no doubt as to the propriety of circumcision in all cases of elongated prepuce with contracted orifice; and the necessity for the operation should be represented to parents even in the absence, at the moment, of painful symptoms. In simple elongation, if there is the least difficulty in exposing the glans, it is better to err on the side of operative interference.

If phimosis is associated with nocturnal incontinence of urine, it is far better at once to circumcise the child than to waste time in the constant administration of the various remedies prescribed for this condition. In cases of sexual incapacity, an elongated prepuce may frequently be shortened with good effect, and certainly, if with the elongation there is contraction of the orifice, circumcision should be recommended. Phimosis, the result of a balanitis, may of course be reduced by simple remedies, such as fomentations, hot baths, and injections; but if there is suspicion of a chancre beneath, it is better at once to expose the glans by the slitting operation. *See* CIRCUMCISION.

In cases of acquired phimosis, especially in old men, the malformation may frequently be remedied by dilating the parts either with a pair of forceps, or by a screw dilator especially constructed for the purpose. The operation may, in some cases, be facilitated by incising the orifice at two or three points with a narrow-bladed knife. PAUL SWAIN.

PHLEBITIS.—An inflammation of the veins.

Causation and Pathology.—The most purely surgical form of phlebitis is that induced by wound or contusion—traumatic phlebitis. The idiopathic form most nearly resembling this is that occurring after parturition, where the inflammation in like manner spreads directly from the open mouth of ruptured vessels, subsequently to separation of the placenta. Apart from this, acute phlebitis is almost invariably secondary either to thrombosis or inflammation of the surrounding structures, the primary changes in the former case taking place in the inner coats, in the latter in the adventitia, later becoming general. Chronic inflammatory changes may, as in the arteries, be primary, and are then due to anomalies in the force and rapidity of the venous circulation; as would be expected, however, from the less variable nature of these conditions in the veins, chronic endo-phlebitis is a much less common or serious disease than the corresponding arterial change. The inflammation may be local or adhesive, diffuse or

suppurative, in character. Gouty and tubercular phlebitis are also spoken of.

Adhesive phlebitis is seen in its purest form in cases of wound. By this process the necessary obliteration is effected after wound; it is seen also in cases where thrombosis is followed by organisation. *See* HÆMORRHAGE; THROMBOSIS. Suppurative phlebitis may be secondary to suppurative of a thrombus, or to extension of inflammation from without. It is diffuse in character, and its causation resembles closely that of pyæmia. When periphlebitis occurs secondarily to cellulitis, the adventitia is principally affected; the vein is often dissected out by surrounding suppuration, and under these circumstances may slough. This is of importance, as in these cases complete thrombosis is often absent, so that hæmorrhage may result. The coats of the vein are thickened by infiltration with inflammatory new-formation, stiff, of a yellow or yellowish-grey colour, the intima opaque and more or less deeply tinged with red. This condition may extend over a large area. Besides the diffuse form of suppurative phlebitis, localised suppuration may occur in cases of adhesive phlebitis, either the clot breaking down at its centre or the change being entirely perivenous; in these cases, a well-developed clot usually exists on either side of the suppurating point, excluding the dangers of septic infection and hæmorrhage. Chronic endo-phlebitis is most common in cases of varix; usually the veins here are generally thickened, and, on examination, the intima may be more or less opaque, presenting in addition ill-defined yellowish patches, slightly raised by infiltration beneath. These patches of fatty or atheromatous degeneration are often accompanied by the presence of small calcareous spicules. In acute miliary tuberculosis, tubercles may be deposited beneath the intima, and in chronic tuberculosis of organs, the veins may become implicated by direct extension. Should a breaking-down mass in this way directly open into the general circulation, it may be the source of a general miliary tuberculosis (Weigert). No special pathology yet exists for the gouty phlebitis of Paget, who says 'the evident disposition towards being metastatic and symmetrical . . . is strongly in favour of the belief that the essential primary disease is not a coagulation of the blood, but an inflammation of portions of the venous walls.'

Symptoms.—These differ widely according to the local, or diffuse and septic character of the inflammation.

LOCAL PHLEBITIS.—This is most frequently met with secondary to injury, or in cases of varix, and then in the lower extremity. The first symptoms are usually pain and swelling, accompanied by interference with the function of the limb; the other cardinal signs of inflammation, heat and redness, will be present in varying degree. Pain, increased by use of the limb, in some cases slight, in others of a severe neuralgic character, often severe in thrombosis of deep veins with subfascial œdema. Swelling, due chiefly to œdema, in part to inflammatory changes in and around a vein. The character of the swelling varies with the affection of superficial or deep veins. If the superficial veins, there is local œdema of the area from which the blood-supply is gleaned, and a hard cord or knotty tumour corresponds to the thrombosed vein. If the deep veins, there is general œdema of the limb, of a tense white character, often not sitting on pressure, and accompanied by considerable enlargement of the superficial veins. Redness, of a bright or purplish character, may extend over the thrombosed veins, if superficial; it is usually developed subsequently to the pain and swelling. The temperature of the limb may be raised generally, or locally over the patches of inflamed veins. When local suppuration occurs, the usual signs of abscess-formation will be present.

These local symptoms will be accompanied by those of a general febrile condition of varying intensity, usually not severe, the temperature rarely rising above 100° or 101° Fahr. The marked characteristics of the symptoms in gouty phlebitis are the tendency to metastasis, already referred to, and its patchy distribution.

DIFFUSE SUPPURATIVE PHLEBITIS.—In these cases we have the signs of diffuse cellulitis, accompanied by symptoms of general infection. The most frequent examples of the condition are met with in pyæmia; hence, it occurs frequently in like manner after injury to bones or veins. It may start from a wound, or may occur without any local breach of surface. The local signs again depend on the superficial or deep situation of the vein affected: if superficial, there will be œdema, diffuse, dusky redness and pain, often unaccompanied by local evidence of clot-formation, followed by rapid suppuration and extensive sloughing. If the deep veins are affected, superficial discoloration may not occur, but actuation and signs of deep suppuration appear early; in some cases, gangrene of the whole thickness of a limb may rapidly

supervene. The general symptoms are those of septic cellulitis with constitutional infection. The temperature is continuously high, as in septicæmia (103°, 104°, 105° Fahr.), or there are frequent rigors when metastases occur. The patient is depressed, sleeps badly, is often delirious, the delirium being of a wandering character. The tongue is furred and dry, the teeth and lips become rapidly covered with sordes, diarrhœa often sets in, and the patient dies in a typhoid condition.

Prognosis.—In adhesive phlebitis the prognosis is good as to life, and, locally, permanent obstruction of the vein is uncommon except in the case of varicose veins; here such a result is to be regarded favourably, as effecting a spontaneous cure. If the vein is obstructed and sufficient collateral circulation is not set up, permanent œdema may more or less interfere with the functions of the limb. Diffuse suppurative phlebitis is, on the other hand, extremely serious, the patient as a rule dying of SEPTICÆMIA or PYÆMIA.

Diagnosis.—The diagnosis of phlebitis from simple thrombosis depends on the absence of local or general inflammatory symptoms in the latter. Lymphangitis presents considerable resemblance to phlebitis. The chief distinguishing points are—(1) the primary origin—in lymphangitis in a sore, in phlebitis often in a varicose vein; (2) the early enlargement of glands in lymphangitis; (3) the bright rosy tint in lymphangitis, appearing prior to the œdema, also its tendency to spread in a spiral line, in phlebitis the tint usually being darker, the blush appearing subsequently to the œdema; (4) the extent of the œdema in phlebitis; (5) the presence of a hard cord in phlebitis.

Treatment.—The treatment consists in giving rest to the part, and affording all possible aid to the impeded circulation. The patient should be confined to bed, the limb raised, and loosely bandaged. If there be much pain, the limb may be enclosed in warm cotton-wool sprinkled with belladonna liniment, or with lint on which equal parts of belladonna extract and glycerine have been spread. The bowels should be kept acting freely, and any source of constriction or vein-pressure, if possible, removed. In the later treatment, elastic pressure, to support the limb and promote absorption of effused inflammatory products, should be employed. In the case of thrombosis, a piece of emplastrum ammoniaci c. hydrargyro, applied over the spot, often promotes absorption. In cases of diffuse suppurative phlebitis, treatment is of

little avail; stimulants must be given freely, and if the removal of the inflamed area be possible, amputation may be performed to remove the local infecting centre.

G. H. MAKINS.

PHLEBOLITH.—A calcareous concretion developed within a vein. Phleboliths are the result of calcareous degeneration of laminated thrombi; they are met with chiefly in the veins of the lower extremity and pelvis, most commonly lying loose in ampullæ behind the valves. They are usually rounded or oval in shape, and are constituted of phosphate of lime with twenty per cent. of protein matter and a little sulphate of lime and potash (Frankland).

G. H. MAKINS.

PHLEBOTOMY. See *VENESECTION*.

PHLYCTENULAR OPHTHALMIA.
See *CONJUNCTIVA*, Diseases of the.

PHOSPHORUS NECROSIS. See *JAWS*, Diseases of the.

PHOTOPHOBIA, a dread of light, is a common symptom of inflammation or other disease of those parts of the eyeball and its appendages which are innervated by branches of the fifth nerve. See *CONJUNCTIVA*, Diseases of the; *CORNEA*, Inflammation of the; *IRIS*, Diseases of the.

PHTHIRIASIS.—The eruption produced by lice. See *PEDICULL*.

PIGEON-BREAST.—A malformation of the anterior walls of the thorax, which may result from various causes. The upper half of the thorax may be quite normal, but from sudden depression of the infra-mammary regions after whooping-cough, partial collapse of the lungs, &c., the lower half of the sternum, with the contiguous rib-cartilages, become unduly prominent.

Another variety, which best deserves the name of pigeon-breast, is when the whole thorax is much narrowed from side to side, with the sternum presenting, instead of a plane surface, a convex one transversely; this is apparently of congenital origin, but becomes worse as the child grows.

A third variety is due to giving way or bulging of the sternal rib-cartilages, leaving the sternum in a hollow; sometimes there is actual hollowing out of the sternum, exactly reproducing what is known as boot-maker's chest, which is the effect of the pressure of the 'last,' against which the man presses while at work. This variety is more often unilateral than the others, as the

rib-cartilages on one side may be quite normal, while those on the opposite side project an inch or more beyond the normal surface of the thorax. The anterior ends of the sternal ribs may participate in this bulging of the rib-cartilages.

A variety of pigeon-breast accompanies severe spinal caries, with much deformity of the dorsal vertebræ; here the sternum is thrust forwards, especially its lower half, with the adjoining rib-cartilages and ribs.

Pigeon-breast, not due to spinal caries, is nearly always associated with exaggerations of the antero-posterior curves of the spine (see *ANTERO-POSTERIOR SPINAL CURVATURE*), and is not infrequently found in lateral curvature.

Pathology.—In opposition to some authorities, who maintain that pigeon-breast is always due to rickets, Sir W. Jenner says that 'it very often arises from other diseases than rickets, but the two varieties are very easily distinguished. In rickets, the deformity is due to the softening of the bones, which yield at their growing ends and push forward the sternum as a rounded prominence, and the outline of the chest is a double curve. In pigeon-breast from non-rickety causes, the yielding of the ribs takes place where there is a natural maximum bend—at their angles, the sternum is pushed straight forward, and the outline of the chest is angular' (the pigeon-breast of spinal caries *par excellence*). It is, therefore, due to rickets and other affections causing softening and yielding of the bones, especially when associated with lung-trouble, as acute and chronic bronchitis, whooping cough, &c.; also with partial collapse of the lungs, caused by deficient expansion of the thoracic walls from enlarged tonsils obstructing the entrance of the air into the lungs.

This deformity is nearly always one of infancy and childhood, and is often overlooked until it gradually becomes so bad as to attract attention.

The *prognosis* as to the effect of treatment depends upon the amount of improvement immediately effected by placing the patient in the erect position, with the arms extended upwards by the side of the head. Apparently very deformed cases, especially when due to falling-in of the infra-mammary regions, can thus be almost completely restored temporarily to a normal configuration. The earlier treatment is commenced, and the more yielding the chest-walls, the more satisfactory will be the result.

Treatment.—Nothing can be done for the deformity of pigeon-breast due to spinal

caries; but considerable relief can be given to the patient's want of breath and sense of fatigue, by developing those portions of the thorax which are still movable, by means of the treatment described below. Necessarily, the spinal caries must be cured by healthy bony ankylosis before attempting anything for the chest-trouble.

In pigeon-breast due to other causes, the first thing is to correct any spinal deformity present (*see* LATERAL and ANTERO-POSTERIOR SPINAL CURVATURE). The next is to enlarge the thorax anteriorly by means of the pectoral muscles, which is efficiently carried out, as follows:—The patient, lying supine, with a small longitudinal pillow between the scapulæ, fixes himself by flexing the knees over the end of the padded table on which he lies, or the pelvis is held on each side by an assistant: the arms are extended upwards by the sides of the head. The surgeon, grasping the hands, resists while the patient slowly flexes the elbows, which should touch the table the whole time, and adducts the upper arms till they are at right angles to the trunk; the patient then slowly relaxes, while resisting the surgeon's efforts to extend the arms to their original position on each side of the head. This exercise is slowly repeated twenty or thirty times, and has frequently a wonderful effect in restoring for the moment a properly shaped thorax. The same exercise can be as readily done by the surgeon sitting with the patient kneeling in front and leaning back against the surgeon's knees, kept close together, covered by a pad or cushion which fits the patient's back between the scapulæ.

Another exercise, to be recommended, is hanging by the hands with the spine and sacrum in contact with the wall, to which are fixed the two pegs the patient grasps; he has then to rotate the spine alternately to the right and left a dozen times. Great care must be taken that no article of clothing is so tight in front as to interfere with the resumption of an improved thorax. Systematic respiratory exercises are most beneficial. In some cases, the surgeon should press in with his hand any undue prominence of the sternum, cartilages, or ribs, while the depressed portion of the thorax is being elevated by any of the above described exercises. If benefit is to be obtained from treatment, a decided improvement will be effected at the end of a month.

The writer saw Dr. Monti of Vienna, some eight years ago, treating pigeon-breast by placing the child in an air-tight bath connected with an air-pump, the face only

of the child being uncovered and surrounded by a broad band of india-rubber. By exhausting the air in the bath the thorax expanded, and, by repeating this daily, considerable improvement was obtained.

BERNARD ROTH.

PILES. *See* HÆMORRHOIDS.

PINGUECULA is the name given to a small yellowish elevation in the conjunctiva near the margin of the cornea, usually at its inner side, more rarely at its temporal margin, but sometimes in each place. It contains, notwithstanding its name, no fat, but is composed of connective tissue and elastic fibres. It is supposed to be due to the irritation caused by small foreign bodies. It rarely grows to a large size, and requires no treatment unless it becomes disfiguring, when it may be removed with forceps and scissors.

H. R. SWANZY.

PIROGOFF'S AMPUTATION. *See* ANKLE-JOINT, Amputation at the.

PISTOL SPLINT.—This has the shape indicated by its name; it is used for Colles' fracture of the radius. The handle is first fixed to the hand and lower fragment, and then the portion corresponding to the barrel is raised to the line of the forearm; by this means the hand is adducted. A short anterior splint, reaching from the elbow to the lower end of the upper fragment of the broken bone, is used with the pistol splint, which should be applied to the posterior surface of the limb.

PITYRIASIS.—The name pityriasis (*P. simplex*) has ceased to convey any definite meaning to the dermatologist, and has rightly dropped out of use altogether. The older writers applied the term to any scaly condition of the skin, the nature of which they did not clearly understand. It may be stated definitely that there is no such disease as pityriasis pure and simple; all the cases so called are simply the later stages of some other disease, such as eczema, steatorrhœa, or lichen scrofulosus.

Pityriasis rubra is a name still in use for a form of exfoliative dermatitis, first described by Hebra, who drew careful distinctions between it and other forms of general exfoliative dermatitis, such as eczema squamosum, general psoriasis, and lichen ruber. The question as to whether or not Hebra was right in his conclusions is still *sub judice*. It is probable, however, that the majority of dermatologists of the present day agree with the late Dr. Baxter

in regarding pityriasis rubra as a very severe form of dermatitis, which may develop from squamous eczema, psoriasis, or lichen, the distinctive characters of these diseases being ultimately lost altogether. With this view the writer in the main agrees. If further observations prove that Dr. Baxter's conclusion is right, it will lead to the general adoption of the name 'exfoliative dermatitis' instead of 'pityriasis rubra,' so that we may ultimately get rid of the word 'pityriasis' altogether. Whatever name, however, we adopt, the disease is both serious and characteristic. In typical cases, the whole body is affected from the sole of the foot to the crown of the head, the skin itself is highly congested, but not thickened nor infiltrated; it is covered with imbricated scales of epidermis, often arranged in wavy rows like scale armour. The dead cuticle sometimes peels off in large pieces, but more commonly the scales shed are small and branny. The degree of exfoliation varies, but it is generally very great, so that a pint measure may sometimes be nearly filled with the scales which rub off in the course of twenty-four hours. The nails generally become uneven and opaque. There is always tenderness of the skin, so that contact with anything gives pain. Itching is not present in all cases. Associated with this condition of the skin, there is always considerable constitutional disturbance and greatly enfeebled vital powers. Not uncommonly there is albuminuria; it has been present in about three-fourths of the cases that have come under the observation of the writer. The *prognosis* in severe cases is unfavourable, a large percentage ending fatally.

Treatment.—This is usually very unsuccessful. Tonics, good food, and rest in bed are, of course, indicated. Simple lotions, such as the linimentum calcis, sometimes give a little local relief to the pain and tenderness of the skin. • ROBERT LIVEING.

PITYRIASIS VERSICOLOR.—*Definition.*—A discoloration of the skin produced by the presence of a vegetable parasite.

Symptoms.—It differs from the other skin-diseases produced by vegetable parasites in that it is harmless, very slightly if at all contagious, and attacks adults rather than children. It occurs usually on the chest and back, in patches of variable size of a yellow or fawn colour, and more or less symmetrical though rarely covering the part uniformly. The patches are slightly raised, and covered, especially at the mar-

gins, with fine powdery scales; and on examination with a lens, the mouths of the hair-follicles will be seen to be much affected. As a rule there is no itching, but very occasionally it is severe. The disease may last for years, and, being harmless, it is only on æsthetic grounds that any treatment is called for. Sweating seems rather to encourage the growth of the parasite, which fact accounts for its prevalence among consumptive patients.

Diagnosis.—It may be mistaken for a secondary syphilide. Other symptoms of syphilis should be looked for, and, should there still be doubt, a careful microscopical examination of scales from the patch would settle the point. The presence of fungus, the scaliness of the patch and its restriction to covered parts, will serve to distinguish it from chloasma; which moreover usually occurs on the face.

Pathology.—Scales, scraped from the patch and placed in dilute liquor potassæ, show, under the microscope, a network of mycelium branching in all directions and groups of large, well-defined spores. The arrangement of the spores in groups is quite characteristic of this fungus, which is known as the *microsporon furfur*.

Treatment.—Thorough friction with soft soap, and the application of any parasiticide. A lotion composed of hyposulphite of soda, 3j. to f3j. of water; or sulphurous acid, 1 part to 4 of water freely applied, or linimentum iodi painted on will easily cure in a few days. If the disease reappears, it is because some particles of the fungus are still undestroyed in the hair-follicles, hence it is necessary to apply the remedies with some energy, and continue them after all apparent signs of the disease are gone. MALCOLM MORRIS.

PLANTAR ARTERIES, Wounds of. These are naturally, owing to the protected condition of the feet, much more rarely met with in this country than wounds of the palmar arches.

Treatment.—This, as in the case of the hand, will vary accordingly as the surgeon is called at the beginning or later on in the case. In the former instance, unless severe hæmorrhage is going on, the effects of careful pressure should first be tried. Thus the surgeon need not spend much time in exploring the wound, but, the main trunks being compressed above, it should be cleaned, and a graduated compress applied, the lint nearest the wound being soaked in Tr. Benzoini Co., carbolic oil, or some styptic, or dusted with iodoform. Before this com-

press is finally secured tightly *in situ*, the toes and foot beyond the wound must be carefully strapped and bandaged, to prevent the painful cedema which is otherwise certain to occur, and which will lead to removal of the compress and recurrence of the bleeding. The compress may be kept *in situ*, by means of two parallel pieces of wood, one above the foot and one below, the two ends of which project on either side, and are secured by strips of handkerchief as in Völcker's plan; and this method will be found useful where no strapping is handy, or where the patient has to be moved any distance. When the patient is in bed, the foot and leg should be kept quiet on a splint, and, if possible, slung in the raised position, with the knee bent, morphia being given subcutaneously. If the surgeon lives at any distance from his patient, it will be well to mark out the femoral artery at the apex of Scarpa's triangle, and to leave a tourniquet very lightly applied.

If hæmorrhage recurs, which is not likely if a compress has been properly applied from the first, the surgeon has to choose between ligature of the dorsalis pedis and posterior tibial arteries, on the dorsum of the foot and behind the inner ankle respectively, and ligature of the femoral at the apex of Scarpa's triangle. The former is by no means certain to prevent recurrence, as the anterior peroneal and internal calcanean, by their anastomoses with the malleolar, tarsal, and plantar arteries, will still bring in blood. Thus, ligature of the femoral will be the more certain method, but this step can only be called for under very rare circumstances.

Where the surgeon is not called to the case till some days after the accident, when recurrence of hæmorrhage is complicated by cedema, cellulitis, and suppuration, and persists in spite of relief to the tension by incisions, the elevated position, and such applications as iced lead lotion, ligature of the femoral is justified, not only for arrest of hæmorrhage, but as likely to cut short the inflammation. W. H. A. JACOBSON.

PLANTAR FASCIA, Contraction of the.—Unlike the corresponding fascia in the palm, that of the foot is very rarely found contracted except in association with certain forms of talipes. Occasionally, however, it is met with either as a congenital affection, though not always marked at an early period of life, or in association with paralysis of the interossei, giving rise to the condition known as 'pes cavus.' At first the deformity is not marked, but, as

the contraction increases, the relation of the bones of the tarsus becomes altered, and the weight of the body having to be sustained entirely upon the heel and the ball of the toe, pain becomes frequent after prolonged exertion or standing. The remedy is to be obtained by freely dividing the contracted fascia subcutaneously, and by the application of a Scarpa's shoe, which should be so constructed as to raise the anterior half of the sole, and to press upon the increased prominence which is given to the dorsum of the foot by the altered position of the bones. This must also be assisted by a strap and buckle passing over the dorsum, and applied to the boot which is to be worn by the patient. See CLUB-FOOT.

JOHN H. MORGAN.

PLASTIC SURGERY.—The various operations of plastic surgery are designed for the restoration of functional usefulness, or for the removal of disfigurements. Of the defects in question, some are due to developmental errors—e.g. cleft palate, hare-lip, extroversion of the bladder, and hypospadias; some to the ravages of disease, such as the destruction of the nose by syphilis or lupus; and others to the immediate or remote effects of physical injuries, as is seen in ruptured perineum and in cicatrices from burns.

There are certain conditions essential to the success of operative procedure:—(1) The tissues concerned must be in a healthy state. It would be useless attempting to fashion a nose where lupous ulceration was still in progress. (2) When the deformity is the consequence of constitutional disease, the surgeon must take care that the general health is such as to warrant the expectation of the wound healing by first intention. Marked syphilitic cachexia contraindicates the performance of operations otherwise expedient. (3) All *tension* upon the parts must be prevented. There are different ways of carrying out this principle. The strain from muscular action is avoided in some cases by division of the muscles. Thus the tensor and levator palati are occasionally cut in the operation for cleft palate, and the sphincter ani in the treatment of fistulous openings involving the rectum and vagina. As a rule, however, it is sufficient if physiological rest is ensured—e.g. by keeping the bowels confined and a catheter in the bladder for several days after suture of a ruptured perineum. In plastic operations about the neck, the head should be fixed by a suitable mechanical appliance. It may be advisable, where the

gap to be bridged over is very wide, to put in deep sutures for the purpose of taking off the strain on the superficial ones. When the operation is for the removal of extensive contraction from burns, subcutaneous division of cicatricial bands skirting the main scar is of great service. In certain instances, lateral incisions are employed to facilitate the coaptation of the freshened edges of clefts or fissures. In the hard palate, e.g., the mucous membrane and periosteum are divided and raised from the underlying bone to allow of easy apposition to the margins of the cleft; or, instead of this, the bony plate is chiselled through, and the septal process in its entire thickness carried inwards on each side in order to secure freedom from tension.

In transplanting skin, as in the construction of a nose, or in the covering in of an extroverted bladder, the flaps should be cut considerably larger—generally about one-sixth—than the spaces they are intended to fit, since otherwise the shrinking from elasticity might entail partial or entire failure of the undertaking. Care must be taken that the bleeding has ceased before the edges are brought together, as the interposition of a blood-clot would tell against the chances of primary union, which is of paramount importance in all plastic operations. For the same reason, foreign bodies should be scrupulously excluded. The raw surfaces are to be brought into accurate apposition, and fixed *in situ* by numerous fine sutures knotted on the sound tissue. If it is deemed desirable, additional means of support can be provided.

The *after-treatment* consists chiefly in keeping the wound protected from injury, and free from the irritation of septic matter. It is a good plan, when practicable, to cover the part with oiled silk, and this with moistened boracic acid lint or iodoform wool. To retain the dressings in place, collodion is preferable to strapping, as it exercises no injurious pressure, whilst it more effectually prevents the ingress of atmospheric impurities. Where the wound, however, is of mere linear extent, it is sufficient to support it, and paint it over with flexile collodion. It may be mentioned that where healing by the first intention is not obtained throughout the entire wound, cicatrization should be encouraged by grafting, snippings being taken from the skin for that purpose.

After union has taken place, attention should be directed to the cicatrix, which is liable to undergo stretching on the one hand and undue contraction on the other.

Either of these events may frustrate the purpose the surgeon had in view.

Causes of Failure.—Neglect of one or more of the above-mentioned provisions may end in want of union, primary or secondary. Other causes of failure are erysipelas and secondary hæmorrhage, accidents to which all wounds are liable. In transplantation of skin there is always some danger of sloughing, consequently, when gliding or torsion is employed, it is necessary that the pedicle or base of vascular supply be of ample width, in order that the vitality of the flap may be ensured.

Methods of Procedure.—The primary plastic operations fall practically under five heads, three of which relate to transplantation of pieces of skin from adjacent or distant parts. (1) The Italian or—as it is named after the surgeon who introduced it—the Tagliacotian method consists in freshening the surface and margin of the area to be covered, and fixing there a flap of skin raised from another part of the body; thus, in the construction of an eyelid, the graft is taken from the hand, which is kept applied to the face until the supply of blood from the pedicle of the flap is no longer required. The pedicle is then divided. The operation is seldom practised, since it necessitates restraint of movement, which is irksome to the patient. It has one advantage—viz. the pedicle can be made as wide as desired, so that sloughing is effectively guarded against. (2) The Indian operation is generally selected in preference to the Italian. The flap is dissected from the skin immediately bounding the part to be constructed or restored, and is placed in position either by gliding or torsion. The latter plan is carried out in the operative treatment of ectopia vesicæ. Burow's operation combines excision and gliding, the object being, not only to close a gap in the skin, but also to minimise and distribute the unseemliness resulting from contraction of the cicatrix. It is admirably adapted for the removal of scars and rodent ulcers of moderate size. (3) Wolfe has shown that portions of skin can be successfully excised and grafted on to freshened surfaces. He recommends that all the subcutaneous fat and areolar tissue from the graft should be removed with scissors. The operation must be performed rapidly, and with scrupulous attention to cleanliness. (4) Fissures or clefts are closed by freely paring the edges, bringing them into accurate apposition, and fixing with sutures, harelip-pins, &c. (5) Fistulous openings are usually treated by paring the

edges, raising the skin from the subjacent tissues, and causing it to glide over the aperture to be obliterated. See RHINOPLASTY.

Recent experiments have shown that, in the lower animals, strips of bone with the periosteum attached can be successfully grafted on to living tissues, where they are capable of setting up osteoplastic growth. It remains to be seen how far this measure will be serviceable in the surgery of the human being. See GRAFTING.

AUGUSTUS J. PEPPER.

PLEUROSTHOTOS. See TETANUS.

PLUGGING THE NOSTRILS. See EPISTAXIS.

PNEUMOCELE, or HERNIA OF THE LUNG, is the protrusion of a portion of the lung through a wound involving the pleura. It is divided into the *immediate* and *consecutive* forms.

In the *immediate* form, the lung protrudes directly from the wound, either immediately after the injury or within a very short period. It may be complicated by a wound of the lung, though this is not a necessary accompaniment. It probably arises from the patient making a powerful expiratory effort, with the glottis closed, at the time of the receipt of the injury, the thoracic wound itself being almost necessarily an incised one. The air not being able to escape from the lung, this viscus itself is forced in the direction of least resistance, which will be through the wound. When expiration takes place, the ribs descend, the intercostal spaces narrow, and the piece of lung extruded remains shut out of the cavity of the chest. As the circulation in the blood-vessels, more especially in the veins, gets impeded by the pressure, rapid swelling of the extruded mass takes place, and the hernia becomes irreducible. Under these circumstances it presents a bluish-black mass, which consists of the lung covered over by its own investment of pleura; this, as the congestion becomes greater, assumes almost a black appearance. It generally, however, retains its vitality for a lengthened period, but may, if the congestion be very intense, die and slough off at the point of constriction, leaving a granulating sore which pretty readily cicatrises. The lung remains adherent to the parietes at this spot.

Treatment.—The prognosis in these cases is favourable. If the patient be seen sufficiently early, an attempt may be made by gentle manipulation to reduce the hernia, great care being taken not to damage its delicate vesicular structure in so doing. If

this be found impossible, the neck of the constriction may be cautiously divided on a director, care being taken to avoid wounding the intercostal vessels. The manipulation for reduction should then be repeated. The advisability of reducing the hernia must necessarily depend upon the state of the extruded piece. If the congestion be very intense, leading to the belief that there will be great risk of sloughing, it will be best to leave it *in situ* to separate by the natural processes. Or, if these are too long and tedious in their course, they may be expedited by surrounding the protruded mass with a ligature, or even by cutting it off. In the latter case the risk of hæmorrhage is considerable, unless the process of sloughing has already proceeded so far as to obliterate the vessels.

In the *consecutive* variety of hernia of the lung, the protrusion does not take place till some weeks after the infliction of the injury, when the wound is already cicatrised. The hernia will here be covered over by the thinned integuments, forming a doughy, pulpy mass of the normal colour of the skin. The manner of its production is probably the following. The wounded lung becomes adherent at the point of injury, which undergoes a chronic inflammatory process all around, and hence, as all inflamed tissues are weaker than healthy ones from having lost their resisting power, the whole area of the chest parietes about the wound will be weaker than usual. The lung itself, from constant coughing, as well as from the injury, becomes swollen and emphysematous, and hence tends to protrude in the direction of the least resistance, which will be towards the injured part; where its constant pressure may even cause absorption and thinning of the parietal structures, just as an aneurism does.

The *prognosis* of cases of pneumocele is favourable. The *treatment* consists simply in protecting and supporting the hernia. This may be done by some variety of truss, contrived specially to suit the nature of the case.

A special form of immediate pneumocele is occasionally seen without external wound, when the walls of the chest have been so badly crushed that the ribs have become comminuted. The intra-thoracic injury in these cases is so severe as almost always to lead to rapid death.

Congenital pneumocele is also sometimes seen. The affection is very rare, and the treatment will be the same in principle as for the consecutive variety.

H. G. HOWSE.

PNEUMONIA, Traumatic.—Inflammation of the lung, from injury to this viscus, may be due either to an external wound, to a wound produced by a broken bone, or to the harm wrought in the organ by a severe squeeze, whether producing actual rupture of the tissue or falling short of that point. The symptoms are much alike in all three cases, but the prognosis will be much more grave in the case of an external wound than in the other two, in which, as a rule, the prognosis may be regarded as favourable, if the amount of tissue involved be not very great.

The *signs* of an acute pneumonia, occurring after injury, will be much the same as in idiopathic pneumonia. But it will generally be preceded by the expectoration of frothy, light-red blood from the injured part of the lung; and this will gradually change, in from thirty hours to three days, to a rust-coloured sputum, as the pneumonia becomes established. In an ordinary acute idiopathic pneumonia, there is not the same expectoration of frothy, light red blood. There may be a small amount of white frothy sputa in such cases, but this very rapidly changes to rust-coloured expectoration. In cases of doubtful injury this may help to clear up the point, though it is not an absolute rule.

In addition to the expectoration, there will be dulness over the affected part of the lung; this may spread far beyond the actual injury. Auscultation will give in the first place a fine silky crepitation, due probably to the blood effused in the vesicular tissue of the lung,—but rapidly changing to coarse crepitant râles, as the lung becomes solid and permits the movement of the air and mucus in the large tubes to become audible. There will then be more or less bronchial breathing and bronchophony audible over the affected part, and the vocal fremitus will be increased. In the severer cases, the temperature may rise to 102° or 103° F., and the pulse in proportion. The respiration will be hurried out of proportion to the pulse, on account of the diminished breathing area available. In cases such as these, it is obvious that the disease may pass on to a fatal issue, if the injury be severe and the amount of lung implicated be considerable. More especially is this likely to be the result, if the condition of the other viscera (kidneys, liver, &c.) be not perfectly sound at the time.

The *prognosis* in these cases is generally favourable, if the amount of lung-tissue involved be not very great. The dulness

becomes less marked; air is again heard entering the vesicular tissue on auscultation, the bronchophony and bronchial breathing disappear, and the expectoration loses its rusty colour and finally ceases.

The *treatment* of these cases does not require to be of an active nature. In the first stage, that of hæmorrhage from the lung, it will be necessary to give the patient as little food as possible, so as to limit the tendency to extravasation of blood. The length of the subsequent affection, and its severity, will very much depend upon the amount of blood effused, and the area of lung-tissue thus involved. The patient should be kept in bed, and at perfect rest, and the tendency to cough diminished as much as possible. In the second stage, when the hæmorrhage has ceased, this may be aided by keeping the patient in a warm moist atmosphere. The writer has found that nearly all hospital patients, in this condition, experience great relief from being placed in a tent with a steam-kettle. During both the first and second stages, benefit is derived from the administration of antimonial wine in some such form as the following:—℞ Vini antimonialis ℥x.; Tinct. camph. co. ℥xx.; Liq. morphine hydrochlor. ℥xx.; Liq. ammoniæ acet. f3ss.; Aq. chlorof. ad f3j. Ft. haustus, quartis horis sumendus.

In the last stage, that of resolution, all medicine may be suspended, and the inflamed lung allowed to take its own course. Even in this stage the diet should be very carefully regulated, for the resolution of a considerable mass of inflamed tissue is a tax upon the powers of elimination, and hence involves work for the excretory glands, which, if not in a perfectly sound condition, they may have a difficulty in performing.

Should the pneumonia be due to an external penetrating wound, the treatment would be that described under the head of LUNG, Wounds of the. H. G. Howse.

PNEUMOTHORAX is the condition in which air fills the pleural cavity, the lung collapsing to a degree corresponding to the amount of air entering the pleura. In medical practice, it is most frequently caused by disease of the lung of an ulcerative character—e.g. the perforation of a tubercular cavity into the pleura, or by gangrene of the lung. In surgical practice, cases mostly arise from external injury, the air either entering from without, as in perforating wounds of the thoracic parietes; or from the lung itself, where this viscus

has been wounded. These wounds may be caused either by the pointed end of a fractured bone, most commonly a rib, or by some external penetrating agent.

Pneumothorax is more common in the adult or those past middle age than in young people. The reason of this is that, where the lung is healthy, there is less tendency in the surfaces of the pleura to fall away from each other than where atrophic or senile changes are impending. Thus, in some incised wounds of the chest, where the lung is clearly exposed, pneumothorax does not take place, the exposed lung remaining in apposition with the sides of the wounded pleura, and moving in each act of respiration. In such cases, the coaptation of the surfaces of the pleura seems to neutralise the natural tendency of the lung-tissue to contract. In paracentesis thoracis for serous effusion in young people, the tendency to pneumothorax is much less than in the same operation for empyema. The reason of this probably is, that in cases of empyema the lung itself more frequently becomes diseased, and hence loses its elastic resiliency, while the tendency to elastic contraction becomes proportionably greater.

The *signs* of a pneumothorax, whether resulting from disease or accident, are similar, and cannot well be overlooked in any careful examination of the chest. In the first place, there is drum-like resonance on percussion over the whole of the chest. The only exceptions to this rule are where a previous pleurisy has caused partial adhesions of the pleura, so that the pneumothorax does not spread over the whole of the pleural cavity. In such cases, there may be local tympanitic resonance, but elsewhere the ordinary percussion note of the lung is present. On the other hand, tympanitic resonance is very often found in the upper part of the chest-cavity anteriorly, where there is serous or purulent effusion in the pleura without any pneumothorax. This is due to the lung being pressed up towards this part by the effusion, the air confined in the vesicles giving a tympanitic note similar to that found in emphysema.

All such cases of doubt in the *diagnosis* of pneumothorax can be solved by the application of the next test—viz. auscultation. On placing the stethoscope over the chest, it is at once noted that the breath-sounds are inaudible, or extremely distant. In some cases, however, where the distension is very great, the breath-sounds from the opposite side may be heard, carried along the tight walls of the cavity. Such cases may be distinguished by another

test—viz. inspection of the chest (vide *infra*). On shaking the patient or changing his position (succussion test), a noise is frequently heard like the striking of two small pieces of coin together (metallic tinkling). This is due to the falling of a drop of fluid from one part of the cavity to the other, or the bursting of a bubble of air, the sound being exaggerated by the drum-like distension of the walls. It is occasionally produced in a cavity *within* the lung-tissue, as in a large tubercular cavity, but never so distinctly as in a pneumothorax: such cases are also readily distinguished by the absence of the drum-like resonance on percussion over any considerable area.

In cases of extreme distension, inspection of the chest may afford valuable information. The walls will be found bulged, the intercostal spaces projecting, and the affected side scarcely moving at all in the act of respiration. This test is especially valuable, as indicated above, where the distension is so extreme as to cause the breath-sounds of the healthy lung to be heard over the affected side. But all degrees of distension exist, and, even in the slighter cases, there is a very marked difference in the mobility of the affected side as compared with the sound one.

Treatment.—From whatever cause arising, pneumothorax, if it does not induce symptoms of considerable distress to the patient, had best be left alone. If it be due to a temporary cause, such as wound of the lung from a fractured rib, the air will probably be absorbed, and the lung will have a good chance of again expanding. Even in some of the medical cases, where it takes place from the perforation of a tubercular cavity, the partial collapse of the lung resulting from it, if it does not have a quickly fatal issue from disturbance of the respiratory area, occasionally results in good to the patient, from checking the progress of the tubercular ulceration, by allowing the parts concerned much more complete rest after collapse than was possible before. It is only in cases where pneumothorax causes great distress to the patient, or where death is impending from pressure upon the lung, that operative measures should be adopted for its relief. These should consist in puncture of the cavity containing the air with a fine trocar and canula, allowing the air to escape freely till equilibrium is re-established. The small canula should then be withdrawn. Immediate relief will be obtained in this way, and the operation may be repeated as often as necessary. This is better than leaving the canula or a

drainage-tube in the wound, unless there is much fluid mixed up with the air, when the drainage-tube becomes desirable for the sake of allowing its escape, and partly also for the sake of washing out the cavity—especially if the contents are fetid.

The *prognosis* of every case of pneumothorax is grave. Very speedy death often takes place in the cases where it results from tubercular ulceration, but, if the patient survives two or three days, life may be prolonged for weeks or months, death finally resulting from a spread of the tubercular disease. The cases in which the prognosis is most favourable, are those in which pneumothorax is due to a fractured rib. The first shock of the injury having passed away, the air generally absorbs and the patient does well. H. G. HOWSE.

POISONED WOUNDS.—The expression 'poisoned wound' is here employed to denote the condition of a wound secondarily infected by a parasitic or other virus, but the term does not include such cases as insect and snake stings or bites, or the special lesions produced by various mineral poisons, though these may be alluded to. In fact, whenever a wound is followed by acute inflammatory mischief spreading from it as a centre, such mischief not being caused by one or other of the rarer animal or mineral poisons mentioned above, it would come under the present heading. It very rarely happens, however, that a patient is attacked by one variety of septic disease at a time, so that it is impossible to define the above expression more closely; and besides, the decomposition-products of one poison, being poisonous in themselves, will give rise by their own action on the system and tissues to an additional train of symptoms. On account of all this complication surrounding the causation of poisoned wounds, the diseased conditions will be simply described according to the ordinary anatomical arrangement of the tissues they attack.

Etiology and Theory of Causation.—It will be best to allude briefly to that theory of the action of the poison, in these cases, which finds most favour at the present day, before discussing the conditions which predispose a patient to suffer from a poisoned wound. Since it is found that, in every case, the wound is contaminated with some filth or other, whether it be fluids from a corpse recently dead, dirt, or any decomposing albuminous matter, it is now assumed, by most writers, that the poison is either one of the chemical products

of decomposition or an actively growing pathogenic and parasitic organism. For discussion of the mode in which these poisons, chemical and living, are supposed to act, reference must be made to SEPSIN; SAPRÆMIA; SEPTIC DISEASES; in which the theories of septic poisons are given at length; but we may repeat here that of the two above-mentioned poisons, the simple chemical product of decomposition, sepsin, while giving rise to local changes about to be described, rarely produces general symptoms of 'constitutional disturbance' unless it is absorbed in quantity. See SAPRÆMIA. On the other hand, a living, rapidly growing virus may easily be understood to multiply and spread through the meshes of connective tissue and along the channels of lymphatic vessels, although only a very small quantity may have lodged in the wound. The bearing of this general outline of the causation in each variety of wound-poisoning will be amplified in describing the different forms of the affection, as they are met with clinically. It only remains, therefore, to consider here the general question of predisposition in the individual which renders him open to attack.

If the above theories of local and of spreading poisons are true, then it is obvious that if a person be overworked, and his tissues anæmic and degenerate from insufficient oxidation, as is so constantly observed in town-dwellers, &c., he will form a good nidus for the development of such a virus. Travers, however, showed long ago that this simple idea of predisposition was clearly insufficient to account for the remarkable escapes of many people, who were exposed to the same mischief as others who unfortunately fell victims. The theory of personal immunity has been put forward lately to explain these facts, and is strongly supported by the powerful authority of Sir James Paget; but, beyond drawing attention here to the possibility of some instances of immunity being due to a process analogous to that of acclimatisation—since such persons are usually constantly working in a poisonous atmosphere or handling poisonous fluids—it cannot be further dwelt on here, and will be found fully discussed in the article on SEPTIC DISEASES.

A word, however, must here be said on the kind of wound which is most frequently followed by septic poisoning, and on the various ways in which the poison is inoculated. As is well known, punctured wounds are the most dangerous; the simple

reason being that the elastic skin closes the aperture of the puncture, and prevents the poison being washed out by the natural out slight flow of blood. The poison may be inoculated in one of three ways—by entry into the cell-spaces in the connective tissue, or by direct entry into wounded lymphatics, or possibly into veins. If it is free in the cavity of the wound, it may be absorbed into the lymphatics by the ordinary current into the lymph-channels, or possibly it may be conveyed by leucocytes. If there is tension in the wound, owing to plugging of the orifice with dry discharge or applications, then of course the chance of further absorption is greatly increased. In considering the question of inoculation and absorption too, it will not be forgotten that, as the surfaces of the wound glaze in a few hours, all channels of absorption—e.g. cell-spaces, lymphatics, &c.—are closed in thirty or forty hours by clotted fibrinous exudation; and, unless inflammation has been set up, they will remain impervious to any further absorption of the poison. The valuable effect of disinfectants, referred to at the end of this article, is due to their exciting this closure of the possible channels of entry.

Pathology and Pathological Anatomy.—The former of these subjects has necessarily been alluded to in discussing the causation of these affections, and, as for the condition, it will be best to describe the anatomical changes under each variety.

Varieties and Symptomatology.—The various kinds of septic mischief which may attack wounds, especially those received in post-mortem examinations and dissecting, are perhaps best grouped as follows:—

1. Simple local inflammation of wound.
2. Inflammation of connective tissues.
3. Pustules.
4. Warts and boils—acute and chronic.
5. Inflammation of lymphatics (superficial and deep), and glands—mild and violent.
6. Inflammation of sheaths of tendons (local abscess), and of fasciæ.
7. Periphrlebitis.

1. *Simple Inflammation of a Wound.*—A wound inflicted by a dirty instrument, a stone, piece of coal, &c., frequently festers and inflames. Instead of uniting in a few days, the edges swell, redden, become everted, and discharge a greyish low, sanious pus, which will be found brimming with putrefactive organisms. The inflammation of the wound here is due to the irritation set up by the decomposition of the discharge, and if this is con-

trolled by the use of disinfectants, hot boracic fomentations, &c., the wound soon heals by granulation. See WOUNDS, Treatment of.

2. *Cellulitis around Poisoned Wound.*—The connective tissues in the neighbourhood of a poisoned wound, especially in the forearms and legs, are very liable to become the seat of an acute, rapidly spreading cellulitis. Roughly speaking, this may be divided under three headings, according to the virulence of the poison on the one hand and, perhaps, the resisting powers of the patient on the other. These headings are, briefly, serous, phlegmonous, and gangrenous (see CELLULITIS), the tissues being infiltrated in the first-named variety with a turbid serous fluid, in the second with pus, while in the third class they are sloughy and discharge a foul sanious fluid, which is purulent in the neighbourhood of the sloughs but (like the other two varieties) serous at the spreading border of the inflammation.

Serous septic cellulitis closely resembles Erysipelas in some particulars—e.g. the spreading border, &c., but the following points serve to differentiate the two diseases. Erysipelas begins as an acute specific disease—viz. with an incubation period (twenty-four hours), feeling of malaise, &c., vomiting, rigors, and high temperature. Septic cellulitis steadily (or rapidly, according to the virulence of the poison, &c.) spreads from the wound, as soon as the poison has been inoculated on it. The margin of the inflammation is well-marked in erysipelas, very diffuse in septic cellulitis, and the general constitutional disturbance in the latter (i.e. pyrexia, &c.) is in its course different from that of erysipelas.

3. *Pustules.*—(a) *Acute Form.*—There are apparently two conditions under which a person may be affected with pustules, as a result of inoculation with some septic poison. Thus, the pustules may be solitary or very few in number, and simply situated on the hands, or they may be multiple and scattered over the surface of the body, as well as those parts which are exposed to direct contamination. The solitary pustule is, sometimes, the result of inoculation in a small crack at the side or on the dorsum of a finger, while, at others, it clearly follows the introduction of the poison into a hair-follicle or sebaceous gland. Consequently, the dorsum of the proximal phalanx is a frequent seat of such pustulation.

The acute form of pustule runs a fairly definite course. A few hours after exposure

to the poison (such, for instance, as putting the unprotected hand into some septic serous exudation, &c.), an infected spot will be felt to itch, the itching stage lasting three or four hours; the part then begins to ache, but before pain is felt it will be found to be reddened. In twelve to twenty hours it swells, and movement of the finger becomes very painful. In thirty to forty hours the centre of the pimple suppurates and forms the typical pustule. If the pustule at this stage is incised and treated with hot antiseptic applications, it may rapidly heal. If neglected, however, there will ensue a slow spreading inflammation of its base, so that the floor of the minute abscess-cavity is formed by a mass of phlegmonously inflamed subcutaneous tissue. Under these circumstances the pustule becomes chronic.

(b) *Chronic Form*.—In the chronic form, the opening of the pustule is liable to scab over, and, consequently, the exudation from the inflamed base collects again in the cavity and causes pain, &c. It may remain in this state, alternately discharging and closing, for three or four weeks, and ultimately heals by absorption of the inflammatory exudation and by cicatrisation.

Treatment.—(a) Prophylactic. Infection, which produces the pustular form of the disease, can practically always be prevented by covering the skin thickly with carbolic vaseline, which must be well rubbed into the hair-follicles, &c. No greasy material answers so well as vaseline, others, like carbolic oil, &c., being easily rubbed off.

(b) Direct. As soon as the first appearance of inoculation is detected, hot antiseptic fomentations should be applied, and the pustule incised when suppuration has begun. Frequently, if the pustule becomes chronic, it may be made to heal speedily by touching the floor of the small cavity with nitrate of silver.

4. a. *Warts*.—The so-called post-mortem room wart, or—to use the term suggested by Dr. Wilks—‘*verruca necrogenica*,’ is a curious condition of the dermis, which often is a relic of a pustule as just described, but sometimes begins, more or less insidiously, from the poisoning of a crack in the skin. When it begins as a pustule, it is practically an extension of the indurated base of that lesion. The induration spreads to neighbouring parts, especially over the knuckles; the epithelium, thickening here and there, forms warty ridges, the furrows between often appearing red and sometimes exuding a little serous fluid. If the warty epithelium is picked off, the papillæ beneath

often bleed a little. In the process of healing, the cracks, &c., gradually dry up and heal, the thickened epithelium scaling off. This condition, though usually attributed to the direct effect of putrid substances, may, perhaps, in some instances be started by some of the powerful metallic salts used as disinfectants, and a predisposition produced in the tissues by the free handling of freezing mixtures (e.g. ice and salt, &c.), used in the preservation of tissues, &c. It is an exceedingly obstinate affection and very often remains unchanged for several years, or alternately heals up and breaks out again.

Treatment.—(a) Prophylactic: see *Pustule* above. (b) Direct. The best immediate treatment is to keep the part constantly covered with some antiseptic but not very irritating ointment (e.g. boracic vaseline, &c.). If the epithelial thickenings are considerable, they often can only be reduced by the continuous application of wet boracic lint.

4. b. *Boils*.—Between the strictly local affections, just described, and the general infection of the lymphatic system, about to be mentioned, there is a class of partly local, partly general, inflammatory lesions which are boils, although their mode of origin is often peculiar. Practically the condition amounts to this, that a pustule is found in the ordinary way above described that this pustule soon becomes (by formation of a central slough or core) a boil of considerable size, and is then followed at various intervals of time (often a week or more) by others cropping out in different places on the affected limb; or they may also appear on the opposite side, probably by direct inoculation rather than generalisation of the poison. These boils customarily become fully developed in a few days (three to four), and when they are incised or spontaneously burst, there is found to be a central core or slough, bathed in pus, surrounded by the connective tissues in a state of phlegmon. If incised before they burst, although tension is thereby got rid of and pain greatly relieved, the central slough still forms as a rule. After separation of the core the cavity heals by granulation. These boils, varying in size, painfulness, &c., may continue to crop out at intervals for several weeks, or even a month or two, sometimes appearing to follow the course of the superficial lymphatics. With the formation of each boil there occur symptoms of general constitutional disturbance—headache, sickness, anorexia, pyrexia—temperature rising to 101°–102°; these symptoms

toms, however, being considerably mitigated towards the end of the attack.

Treatment.—*Prophylactic*, as above directed. *Direct.* The best applications to these boils are hot antiseptic fomentations, while at the same time free incision should be made into the centre of the boil and discharge encouraged. General treatment is of equal importance, and the patient should be given 15 to 30 grains of quinine a day and sent into bracing country air.

5. *Acute Lymphangitis and Lymphadenitis* arising from poisoned wounds, and especially wounds received in dissecting, &c., have been aptly described as divisible clinically into two forms—viz. mild and violent. Practically, this depends on whether the superficial or deep lymphatics respectively are involved; when the former, the affection being comparatively a slight one, but if the latter, a very grave one. In either case, the poison may be absorbed directly into the lymph-stream by means of a slight wound, or more rarely through the (apparently) unbroken skin. It is noteworthy, in considering the mode of inoculation, that this condition is almost always consequent on a very slight wound, and one therefore which, not attracting attention at the time of inoculation, is not treated until too late to prevent the spread of the poison from the point inoculated.

a. *Superficial Lymphangitis and Lymphadenitis.*—*Symptomatology.*—The point inoculated becomes reddened, swollen, and painful in a few hours after inoculation, the pain shooting up the limb from the wound. In twelve to twenty-four hours, the track of absorption of the poison along a main lymph-vessel is shown by a red line or lines, extending from the hand up the forearm to the lymph-gland just above the elbow, and from thence to the axillary glands, which rapidly swell. The pain and line of absorption appear to be as often on the radial and posterior surface of the limb as on the anterior and ulnar, and patients frequently complain of pain along the course of the musculo-spiral nerve, even after active mischief has subsided.

In consequence of the lymphangitis, the whole limb becomes swollen and cedematous. It feels heavy and tense to the patient, who is intolerant of the least pressure on it. At the same time the inflammation of the glands progresses, and by the third day they are greatly swollen and excessively tender; the least movement of the limb, dragging on the fasciæ covering them, causes great pain. General 'constitutional' disturbance, produced either by the direct

absorption of the inflammatory products or indirectly through the irritation of the peripheral nerves, is evidenced by delirium, exhaustion, and rise of temperature to 103° F. or higher, loss of appetite, &c. This condition very rarely terminates fatally where active treatment has been adopted, and the symptoms just described gradually abate.

Treatment.—In the first instance, care must be taken that there is no tension in the original puncture or wound, which should be laid freely open, if necessary, and treated with hot antiseptic fomentations changed frequently (every hour or two), the limb being slung upon Volkmann's suspension splint, or supported on pillows so as to be higher than the patient's body, as he lies in bed. If the patient can bear the more or less necessarily dependent position of the limb, it may be slung in an arm-bath for half an hour or an hour once or twice a day, especially if it has been found necessary to make free incisions. The inflamed glands should be painted over thickly with extract of belladonna and glycerine, and then hot flannel fomentations frequently applied. Of course, as soon as fluctuation with extreme throbbing pain develops in any gland, it must be incised with antiseptic precautions. Relapse of the lymphadenitis is sometimes noticed in these cases, and, consequently, suppuration may be delayed to the end of the first fortnight or even later. The general symptoms are best met by giving quinine in the acute stage, and adding iron as soon as the appetite has fairly returned.

b. *Deep Lymphangitis and Lymphadenitis.*—The affection of the deep lymphatic structures is fortunately relatively very rare, especially at the present time, when the use of powerful disinfectant reagents is beginning to be understood.

Symptomatology.—The condition of inflammation of the deep lymphatics is very rarely accompanied by superficial lymphadenitis, so that it not infrequently happens that the first symptom complained of is pain in the axilla; and this may be diffused and described as being 'in the shoulder,' or referred at once to the lymph-glands. The wound, the seat of inoculation, is usually so small a puncture as not to have been noticed. This was the case in six out of seven cases described by Travers, taken at random. So far as can be made out, there is in these cases a distinct 'incubation period,' averaging forty-eight hours in duration but often less, during which time the patient may feel tired but not ill. Thus it happens that general symptoms begin rather suddenly, at the time when the local

mischievous first attracts attention. About two days or less after inoculation the patient feels extremely ill, frequently has a shivering fit or severe rigor, this being followed by vomiting and a rapid rise in temperature. When the pain in the armpit or shoulder has made itself felt for a few hours, there will be found fulness of the axilla, often reaching up into the posterior triangle and down along the inner side of the arm to the elbow. The swollen area becomes exquisitely tender, and the whole limb tense and insupportably heavy. The inflammation of the connective tissues rapidly increases in the next few days, so that the cedematous fulness extends downwards over the latissimus dorsi, sometimes as far as the buttocks, upwards and backwards over the trapezii, and forwards over and beneath the pectoralis major. Owing, no doubt, to the confinement of the areolar planes between the pectoral muscles, it is here that the tension becomes most severe, and, consequently, pectoral abscess is so common a feature of this condition. The skin over the whole tender area soon becomes intensely congested, and, unless the deep mischief is arrested, it becomes dusky, and vesicles containing a little turbid fluid form on the surface. In fact, there is a very acute serous cellulitis starting from the neighbourhood of the infected lymph-glands, and becoming gangrenous if not interfered with.

The general symptoms, mentioned above, increase rapidly with the development of the local trouble. The most noteworthy point among them is the intense depression of the nervous system, so long as the patient is conscious; delirium is usually present towards evening, and, in fatal cases, death is preceded by coma for twenty-four hours or more. The pulse and respirations vary, of course, in number and quality according to the intensity of the general symptoms, which amount to those of acute SEPTICÆMIA. In a prolonged case pleurisy of the affected side may be present, and sometimes this becomes empyema. Pneumonia is a rarer complication.

Treatment, &c.—The parts which require frequent and careful examination are the borders of the pectoralis and trapezius muscles, as suppuration tends to burrow towards those points. If there are localised spots of very intense pain on deep pressure, incision should be made through the skin, and pus searched for with a director or aspirator needle, the abscess, when present, being freely opened antiseptically. Since free incision liberates the sero-purulent fluid of the cellulitis, as well as the pus and

sloughs of the abscess, it is clear that an early incision can do no harm, if performed antiseptically. As a rule, external applications, such as leeches, fomentations, &c., give little relief, but the latter should not be omitted. Early incision is the principal line of treatment, coupled with large doses of quinine, and salicylate of soda, ten to fifteen grains every four hours, with careful supervision. The latter drug is best given by injection into the rectum in an ounce of milk. Special attention should be paid to the diet, and a proper amount of stimulation by alcohol, ammonia, ether, &c., if the pulse fails. As soon as possible the patient should be removed to country air, early change always being followed by a more favourable condition. In a case where the cellulitis is gangrenous, an attempt should be made to arrest it by hypodermic and interstitial injections, into the border, of hydrarg. perchlor. 1 in 1,000, or of carbolic acid. See HYPODERMIC INJECTION. Complications, such as pleurisy, &c., must be treated on general rules, early aspiration being advisable.

Prognosis.—The termination of such a case will depend, first, on the virulence of the poison, a factor which only reveals itself by the relative violence of the early symptoms. Another factor of extreme importance is the particular susceptibility, or the reverse, which the patient may show towards septic poisons, and, lastly, the state of the patient's general health. If suppuration is detected early and freely liberated the prognosis will be improved. Any sign of duskiness or vesication, indicating that the cellulitis is likely to be gangrenous, is of course extremely unfavourable.

6. *Inflammation of the Sheaths of Tendons (Thecal Abscess) and of Fasciæ.*—A not uncommon consequence of septic puncture of the digits is inflammation of the sheaths of the flexor tendons, but as this presents no special features beyond rapidity of development according to the septicity of the poison, reference must be made to WHITLOW.

Inflammation of the fasciæ and intermuscular septa is, like inflammation of the sheaths of tendons, merely another variety of cellulitis following infective lymphangitis. For the above-named structures possess a very rich network of lymphatics and capillary spaces, being, in fact, great areas for the collection of the lymph. In cases of inflammation of fasciæ, &c., the condition is simply that of cellulitis affecting all the connective tissue structures in the limb, which consequently swells very much, and, on free incision being made, the whole of its loc-

issues are found to be infiltrated with serous. See CELLULITIS.

7. *Periphlebitis*.—This is a very rare consequence of a poisoned wound, but sometimes occurs, and therefore is noted here. See PHLEBITIS.

Summary of Treatment.—The subject of 'poisoned wounds' has been so elucidated during the last few years by the labours of Koch and others, that the lines of general treatment are rendered as easy now as they were difficult when Travers wrote his celebrated treatise on the question. If a person is conscious of having wounded himself under circumstances in which he is likely to become poisoned, he should at once encourage bleeding from the part by constricting the limb or digit on the proximal side of the wound. He should then wash the wound very freely with hot water, and, if it is a punctured one, he should suck

If the poisonous matter is from the body of a person who has died very recently of a highly infectious disorder, such as pueral fever, pyæmia, &c., and the wound be a deep puncture, it would be wise to convert the puncture into a small incision and then apply some disinfectant as follows. After the wound is thoroughly washed as above described, it will be sufficient in most cases to irrigate it thoroughly with 1 in 20 (one per cent.) solution of carbolic acid, and then to dress it with hot boracic lint. If the poison is probably very virulent, a drop of pure carbolic acid should be placed in the wound; but free cauterisation with caustics is to be avoided, as only depressing the vitality of the tissues of the wound. The subsequent treatment of each variety has already been described, and need not be repeated here; but attention may be directed to the fact that it is quite an exception for any variety to be uncomplicated, and that the lines of treatment, indicated above, must be greatly varied to meet the individual peculiarities of each case, care being taken—(a) that the poison be destroyed locally as far as possible; (b) that its absorption by the lymph-stream, &c., be prevented or actively treated if already in progress; and (c) that the patient be treated generally as if suffering from acute PYÆMIA. Prophylaxis has already been referred to under the sub-heading of *Pustules*.

VICTOR HORSLEY.

POLYMAZIA or SUPERNUMERARY BREASTS.—This condition is far more common than absence of the gland. It divides it into three forms—1, supernumerary breasts in the pectoral region; 2,

in or near the axilla; and 3, in distant parts of the body. In the pectoral form as many as five breasts have been observed. The separate glands in these cases are each provided with a nipple, and secrete milk during pregnancy. Two varieties of axillary breast have been described: one entirely distinct and provided with a nipple, and one consisting merely of a separated portion of the normal gland. The second variety is only recognised by its swelling during lactation. Possibly, such outlying portions of mammary tissue may be the true seat of origin of those cases of cancer which apparently commence between the gland and the axilla. Supernumerary breasts in distant parts of the body have been observed in the groin, on the back, on the outer side of the thigh, and elsewhere. In some cases the child has been suckled from these abnormal glands.

MARCUS BECK.

POLYPI.—A polypus may be described as a more or less definitely pedunculated or sessile abnormal projection from a mucous membrane. The precise position of polypi as regards classification is still a matter on which opinions differ; probably truth rests with each side, for many polypi are local hyperplasias in the restricted sense, while others may be regarded as true tumours.

Origin.—The mode of origin of certain polypi, especially those of the stomach and intestines, clearly indicates that they are local hyperplasias.

In the stomach, a mammillated or villous condition, culminating in polypoid growths, is seen as the result of long-continued chronic gastritis, which, by inducing hyperplasia of the submucous connective tissue, is presumably the primary cause of the polypi. Again, in the intestines abundant small polypi are commonly found above strictures; they are usually arranged in parallel transverse lines, and are evidently due to exaggeration of the normal transverse folds of the mucous membrane, parts of which become more prominent, and finally pedunculated. Nasal polypi are frequently associated with a general thickening of the lining membrane of the turbinated bones. On the other hand, in the glandular polypus, which reaches its most typical development in the lower part of the large intestine of children, the new formation of gland-tissue so greatly preponderates over the other constituents that such growths cannot be separated from the adenomata; and can no more be considered local hyperplasias than the glandular proliferous

growths of cystic tumours of the breast and ovary.

Structure.—Polypi are either solid or may be almost entirely composed of cysts; but many chiefly solid polypi contain gland-tissue which, by dilatation of its tubules, gives rise to cysts often only visible with the microscope; and in the mucous polypi cyst-formation results from mucoid degeneration of the connective tissue.

Compound cystic polypi are met with in the cervical canal of the uterus, where, from dilatation and projection of the mucous follicles or glandulæ Nabothi, sessile vesicular masses are formed, which may protrude through the os. Distension of the glandular follicles of the stomach and of the antrum of Highmore also gives rise to polypi composed of a single vesicle.

Minute Structure.—As regards their minute structure, polypi, for purposes of description, may be divided into mucous or myxomatous, fibrous and sarcomatous, fibro-muscular and glandular.

MUCOUS POLYPI.—These form the largest and most widely distributed group, being found in the nose, ear, intestines, bladder, and uterus. *See NASAL POLYPUS.*

Mucous polypi are soft in consistence, succulent, gelatinous, and semi-transparent on section. On squeezing the cut surface small masses of mucus appear, which on removal leave small cyst-like cavities. The polypi are covered with a layer of epithelium of the same form as that of the mucous membrane from which they spring; for example, the mucous polypi of the nose are invested by a double layer of columnar ciliated epithelium. But if the polypi protrude from an external orifice, as may occur in those occupying the nose, rectum, or uterus, the epithelium covering the protruded portion is transformed into the squamous variety. A section of a mucous polypus shows, under the microscope, an interlacement of delicate fibrils, with round, elongated and stellate cells interspersed, the protoplasm of the cells being directly continuous, by means of delicate prolongations, with the fibrils of the stroma. Delicate bands of fibrous tissue traverse the section, and the capillaries are abundant and embryonic. If mucous degeneration is far advanced, the meshes of the stroma are wide, with large gaps formed apparently by solution of the connective-tissue substance. The proportion of cellular elements present in the stroma varies in different specimens and in parts of the same; the round cells may be so abundant as to obscure the fibrillar stroma.

A few gland-tubules can generally be found in the mucous polypi of the nose; in one specimen the writer observed very numerous small, irregularly-massed tortuous tubules lined with very small elongated cells, of which the appearance, together with the characters and arrangement of the tubules, left little doubt that the gland-tissue was newly formed. All mucous-like polypi are not true myxomata, some of those of the intestine being composed of loose fibrous or connective tissue; while many of the so-called polypi of the ear are composed of granulation-tissue.

FIBROUS AND SARCOMATOUS POLYPI.—They occur in the posterior and upper part of the nares and in the pharynx, where they spring from the basi-sphenoid, being intimately connected with the periosteum of that bone, which they sometimes perforate. Some of them are composed simply of fibrous tissue, but, in the opinion of the writer, the majority, and especially those of the naso-pharynx, contain so large a proportion of cellular elements as to ally them with the sarcomata. Their structure is best expressed by the term fibro-sarcoma, the connective tissue being ill-formed, or even homogeneous, and containing more or less abundant round and elongated cells and nuclei, in various stages of transition towards the formation of connective tissue. Ossification may take place in them to a considerable extent. A single pedunculated polypus composed entirely of spindle cells has been observed in the nose. *See NASO-PHARYNGEAL GROWTHS.*

The tendency to hæmorrhage in these polypi may be explained, probably, by the presence of numerous blood-vessels of moderate size, having no proper wall except the furnished by a layer of endothelium, and showing at intervals irregular dilatations.

FIBRO-MYOMATOUS POLYPI.—They commonly occur in the uterus, and, rarely, in the bladder in cases of enlargement of the prostate gland. Their minute structure need not be described here.

ADENOMATOUS POLYPI.—Among these are included polypi largely composed of gland-tissue, such as those situated on the lower part of the large intestine of children. The gland-tissue consists of straight or convoluted tubules lined with long columnar epithelial cells, many of which are distended with mucus or are 'goblet-shaped'. Some of the tubules open on the free surface of the polypus; others are dilated to various degrees. The stroma is scanty and composed of fibrillar connective tissue enclosing round cells, which are most abun-

ant around the tubules. The writer has examined polypi of the uterus containing large proportion of gland-tissue, with aroma of fibrous tissue or of spindle cells.

PAPILLARY POLYPI.—Ranvier describes specimen of nasal polypus, of which the surface was covered with composite papillæ, invested with a thick layer of squamous epithelium.

FREDERIC S. EVE.

POMPHOLYX. See PEMPHIGUS.

POPLITEAL ANEURISM. — 1. *Causes.*—For the general causes see ANEURISM. The following facts probably explain the great relative frequency of aneurism in connection with the popliteal artery:—*a.* Arteries are particularly prone to become the seat of atheroma where they lie in contact with bone, and hence the popliteal artery is very frequently atheromatous, and liable to become aneurismal. *b.* The popliteal trunk is the only part of the main artery of the lower limb that is not well supported by the surrounding tissues. The entire length of the femoral artery is supported by muscles or firm fascia, while in the middle of the ham the vessel is surrounded on the back and sides by soft compressible cellular tissue and fat. *c.* During the free and rapid movements of the knee, the constant changes in the length and calibre of the vessels may predispose to the formation of aneurismal pouchings. *d.* Immediately below the ham the artery breaks up into smaller vessels, lying deeply under muscles by which they are supported or compressed; this may occasion such resistance to the passage of blood into the leg as to favour the swelling of the popliteal vessel just above.

The share which embolism takes in the production of aneurism is not fully determined, but it is obvious that an embolon, entering the main artery of the lower limb, is particularly liable to be arrested at the bifurcation of the popliteal artery, and this mode of origin may account for some cases of aneurism in this situation.

2. *Pathology.*—All varieties of aneurism, except the 'dissecting,' may be met with in the ham; but the various forms of 'traumatic aneurism' are very rare. Fusiform aneurism may be found as a globular dilatation of the whole circumference of the artery, or as a spindle-shaped dilatation of some length of the vessel. A sacculated aneurism may spring from the anterior or the posterior aspect of the artery, and upon this difference depend, in no small degree, the subsequent progress and complications of the cases. Aneurisms springing

from the front of the artery are usually of small size, and are liable to cause caries of the femur or tibia, with destruction of the posterior ligament of the knee-joint, and they may rupture into the joint. Aneurisms springing from the back of the artery grow fast, and reach a large size, owing to the slight resistance offered to their enlargement by the yielding tissues of the ham; they often interfere seriously with the return of blood through the popliteal vein—compressing or even destroying that vessel—and cause severe pain from pressure upon the internal popliteal nerve; they are very prone to become diffused, bursting either subcutaneously or beneath the popliteal fascia. When subcutaneous rupture occurs, the blood rapidly infiltrates the superficial cellular tissue, and the deeper planes as well; when the rupture is sub-fascial, the infiltration of the blood may be more gradual, or quite sudden, spreading up the back of the thigh and down beneath the calf of the leg; if extensive, it quickly impedes the venous circulation, and leads to moist gangrene of the foot and leg. Double popliteal aneurism has been frequently observed, and there are many recorded cases in which the cure of one aneurism has been quickly followed by the development of another in the opposite ham. For the general pathology of popliteal aneurism, see ANEURISM.

3. *Symptoms and Diagnosis.*—The earliest symptom of popliteal aneurism is usually pain in the knee, with a certain amount of stiffness of the joint, which is kept flexed, and hence the patient is very apt to regard his affection as 'rheumatic.' These symptoms may increase, the pain becoming constant and severe, and the movements of the joint more limited. To them may be added pain down the calf of the leg and in the sole of the foot, from pressure upon the internal popliteal nerve; and lividity and œdema of the leg and foot, from pressure upon the internal popliteal vein; while the patient may be conscious of a 'sensation of beating' in the ham. Occasionally the patient can fix precisely the time of origin of the aneurism, on account of the sudden occurrence of pain and stiffness; in other cases the symptoms come on more insidiously. On examining the ham, the surgeon will detect a tumour over, and fixed to, the artery, with an expansile pulsation in every part, and possibly also a thrill accompanying every upheaval of the tumour. On compressing the femoral artery in the groin, not only is the pulsation arrested, but the swelling collapses or yields

under compression to a greater or lesser extent, and then, when the finger is removed from the artery, the pulsation immediately returns with full force in the tumour, which assumes its former size in two or three bounding beats. Auscultation over the tumour reveals a blowing, systolic murmur, which at times may be replaced by a musical or a rasping bruit, and there may be, in addition, a diastolic sound. On comparing the pulse in the tibial arteries of the two sides, that on the side of the tumour will be found delayed behind the other, smaller and weaker. There may be considerable œdema and venous congestion below the ham; frequently there is a certain amount of fluid in the knee-joint, filling out the synovial pouches, and causing 'floating of the patella.' There may or may not be evidence of atheroma in the brachial, temporal, and other superficial arteries, and of hypertrophy of the left ventricle of the heart.

An aneurism being recognised by these signs, the surgeon should proceed further with his investigations, for the purpose of determining its relation to the popliteal artery, the condition of the sac and its contents, and the degree to which the surrounding structures are involved in the tumour. If the tumour be large, of rapid growth, and threatening to become 'diffused,' venous obstruction and pain along the branches of the internal popliteal nerve having been early and marked symptoms, the aneurism is connected with the back of the artery. If, however, the tumour be of small size and slower growth, but attended with constant and severe pain in the knee, while the signs of pressure upon the popliteal vein or nerve are slight or altogether absent; and especially if the pulsation be markedly thrilling, or a distinct line of pulsation, corresponding to the artery, can be felt over the tumour, it is an aneurism springing from the front of the artery. It is this variety of aneurism that is frequently accompanied with synovitis of the knee-joint. If the tumour be clearly defined, firm, with deep pulsation, and but very slightly compressible when the flow through the artery is arrested, it shows that the sac is filled to a large extent with clot; while if the tumour be ill-defined, soft, perhaps fluctuating, with very superficial pulsation, and the tumour can be completely emptied by gentle pressure, when the arterial flow is arrested, it indicates that the contents of the sac are all fluid blood. All intermediate grades between these two extremes are met with.

When an aneurism is noticed to enlarge rapidly, but at the same time its outline

becomes less well-defined, the pulsation indistinct, and the bruit altered in character, the signs point to a giving way of the sac, and a slow leaking of the blood into the surrounding tissues; this may occur beneath the strong popliteal fascia, and, from the pressure of the effused blood upon the vein and nerves, there will be considerable œdema of the leg and foot, and severe pain and numbness. When a patient with an aneurism experiences a sudden sharp pain in the ham, as if he had been struck, followed by a hot trickling sensation in the leg, and general pallor and faintness, while the surgeon finds a sudden and great increase of the swelling, with entire loss of its outline, loss of pulsation and thrill, and great diminution in the intensity of bruit; and if with this there be ecchymosis of the skin, intense œdema, coldness, lividity, and numbness in the leg below, while there is no pulse in either of the tibial arteries, it will readily be recognised that the aneurism has burst subcutaneously, with free extravasation of the blood and complete arrest of the circulation in the limb below.

An aneurism growing from the front of the artery may burst into the knee-joint. This event would be recognised by the sudden distension of the cavity of the joint and the formation of a tense pulsating swelling, which may yield under the hand when the femoral artery is compressed. The introduction of a fine trocar or a grooved needle would, in a case of doubt, show the nature of the fluid. The comparative fulness of the pulse in the tibial arteries shows the extent to which the aneurism interferes with the arterial circulation; the amount of venous distension and œdema in the leg and foot is a measure of the obstruction to the venous return. Even aneurisms of small size may seriously compress the popliteal vein, and ultimately lead to its obliteration. This is a very important point to determine, as, where there is great obstruction to the venous return, any treatment of the aneurism, if attended with occlusion of the artery—and from this possibility no form of treatment is exempt—is very liable to be followed by gangrene. The extent to which the popliteal nerve is compressed by, or involved in the sac of, the aneurism, can be determined by the severity of the pain referred to the leg and foot, by numbness and paralysis. Destruction of the ligament of Winslow and caries of the bones of the knee are recognised by the ordinary signs of these affections, particularly by the severe local pain and the limitation of movement of the joint.

Should the parts about an aneurism become swollen, cedematous, hot, painful, tender, and reddened—the swelling obscuring the outline of the aneurism, and lessening the distinctness of the pulsation—while the limb below retains its former appearance, and the tibial pulse is not lost, the surgeon must diagnose inflammation around the sac of the aneurism. General fever will aid this diagnosis. Should abscess form, fluctuation will be detected, and if an incision be made, masses of blood-clot or fibrin will be discharged with the pus, and sudden profuse hæmorrhage from the aneurism will probably occur in a few hours or days. One other change in an aneurism requires to be carefully recognised, and that is its cure. If spontaneously, or as the result of treatment, an aneurism becomes firmer, and loses its expansile pulsation, its thrill, and its peculiar bruit, it may be held to be solid, and if this condition persist it is cured. If the artery be not at the same time obliterated, there will still be a heaving pulsation in the swelling, and on gently compressing the swelling against the artery, a thud-like murmur may be heard in it. A cured aneurism gradually shrinks, and if this lessening in size be not observed, it affords ground for serious suspicion that there is still some blood entering the sac from the artery.

4. *Treatment*—Except in the conditions named below, when very prompt action on the part of the surgeon is demanded, he will do well to place his patient in bed on a dry and somewhat restricted diet, and keep him under observation for some few days before deciding upon the course of treatment to be adopted. In addition, a thorough examination of the heart, great vessels, lungs, and other viscera should be made. Where the aneurism is of small or moderate size, and its sac contains a fair amount of laminated fibrin, and the patient is placid and submits patiently to the necessary restraint, some form of *compression* should be employed. If the pulsation in the aneurism be readily stopped by flexing the knee, *flexion* should be tried. For this, the limb should be evenly bandaged with a domett from the toes to the ham, and a lithotomy anklet placed on the foot. With the patient lying on the affected side, the knee should be bent to a degree just sufficient to arrest all pulsation in the sac, and it should be fixed in that position by a bandage from the anklet to a band round the waist, and supported by heavy sand-bags laid along the thigh and leg. If the patient complain of the restraint of this position, a subcu-

taneous injection of morphia, gr. $\frac{1}{4}$, should be given. Every few hours the surgeon should examine the aneurism, to feel whether the sac is solid. This should be done without altering the position of the limb. If the patient bear the treatment well, the position may be maintained for four days after the sac is felt to be solid, and then the limb gradually extended, a careful watch being kept upon the aneurism for any return of pulsation. If the restraint be unbearable, the knee may be partially straightened out as soon as the aneurism is felt to be solid, and compression applied to the femoral artery by a Carte's compressor, a bag of shot fastened on the groin, or by digital compression. If the limb be extended and no compression applied to the artery, the clot formed is very liable to disintegrate and the pulsation to return as before. Should no change occur in the aneurism after a fair trial of flexion for forty-eight hours, it may be abandoned. This treatment is not suited to aneurisms of large size, or to those with thin sacs and rapidly enlarging.

For aneurisms of small or moderate size, in patients who are free from internal aneurism, fatty degeneration of the heart, and very advanced arterial disease, *Esmarch's bandage* may be tried with good hope of success. The patient should be prepared by rest in bed, and a dry albuminous diet for a week or ten days. The bandage should be applied from the root of the toes up to just below the aneurism, while the patient is recumbent; or it may be wound firmly round the upper part of the leg only, and then, while the patient stands up, it should be continued obliquely across the front of the knee, and around the lower half of the thigh above the aneurism. The bandage should be kept in place for an hour and a half, pain being subdued by hypodermic injections of morphia or the administration of chloroform. When the bandage is removed, compression of the femoral artery at the groin must be kept up—if the aneurism be not solidified, for twelve hours; if it be solidified, for forty-eight hours, being gradually lessened after the first eighteen hours.

If these methods have failed, or the case be not deemed suitable for them, *simple compression* of the femoral artery should be employed. This is best done by digital compression at the groin, by relays of assistants, who should work in pairs, one having his hand on the aneurism to notice any pulsation in it, and the other compressing the artery with his thumb

with force just sufficient to obliterate pulsation in the tumour; a conical weight or bag of shot pressing on the thumb will greatly facilitate this procedure. Where assistants cannot be procured, Carte's compressors should be used, one being placed at the groin, and one about the middle of the thigh, and used alternately for half an hour, the second being screwed down on the artery before the pressure of the first is relaxed. The skin of the thigh should be washed with spirit lotion two or three times a day, and then carefully dried and powdered, and the pressure employed should not be more than sufficient to abolish all pulsation in the sac below. So soon as the aneurism is found to be solid, the pressure may be relaxed. Continuous compression cannot be prolonged for more than forty-eight hours, but some surgeons prefer to apply it for eight or ten hours a day, merely having a bag of shot bandaged on to the groin in the interval; unless distinct benefit be obtained in a week, this treatment should be discontinued. Should the aneurism continue to enlarge in spite of compression of the femoral artery, or the patient become very restless and irritable, the treatment must be discontinued.

When these measures fail or cannot be carried out, the femoral artery should be *ligatured* at the apex of Scarpa's triangle. Where the patient is of an irritable disposition, and resents confinement and restriction, or where there is reason to suppose that the sac has ruptured, but without free extravasation of blood, this should be resorted to at once; and now that the operation is so much less dangerous than formerly, a patient should not be harassed and worn out with long and repeated applications of compression before resorting to it. If the ligature be followed by dry gangrene, the dead part should be wrapped in iodoform cotton-wool, and allowed to separate spontaneously, the surgeon merely dividing the bone, or trimming up the stump left. If, however, moist gangrene occur, the surgeon must not wait, but *at once* proceed to amputate the limb just above the condyles of the femur.

When the ligature fails to cure the aneurism, and a pulsating tumour is still left in the ham, the surgeon must first of all determine whether the artery be obliterated at the seat of ligature, and if he find it still pervious there, from premature softening of the ligature, he should reapply the ligature close to the same spot. If, however, the artery be obliterated, digital compression of the femoral artery at the groin should be employed, aided by direct compression of

the tumour itself, or Esmarch's bandage may be tried. Should these measures entirely fail, and the patient be young or middle-aged, and with a healthy heart and arteries, the external iliac artery should be tied; if the patient be old, or with a weak or diseased heart, or advanced arterial disease, it would be better to amputate through the lower third of the thigh. Where an aneurism has ruptured externally, or subcutaneously with free extravasation of blood, amputation should be at once performed close above the tumour. Where the aneurism has caused extensive caries of the knee-joint, amputation is also indicated. Should there be evidence of commencing inflammation around the aneurism, ligature of the artery should be performed at once, and the usual means taken to allay the inflammation; if abscess form, an early incision should be made into it, and if hæmorrhage occur from the aneurism, or the aneurism burst into an abscess, the limb should be amputated just above the knee. If the aneurism rupture into the knee-joint, the femoral artery should be tied; should this fail to cure the aneurism, or the joint remain useless, amputation through the thigh is indicated.

A. PEARCE GOULD.

POPLITEAL ARTERY, The, extends from the opening in the adductor magnus, down the back of the knee to the lower border of the popliteus muscle. It reaches from five inches above, to two inches below the knee, bifurcating at the level of the tubercle of the tibia.

Coverings.—1. Skin thin, but pretty firmly fixed. 2. Superficial fascia with but little fat; in this fascia are the small sciatic nerve and the external saphenous vein. 3. The deep fascia, called popliteal, is dense and firm; the external saphenous vein perforates it. Beneath the fascia are the popliteal space and its contents. This is a diamond-shaped space, bounded above by the diverging hamstrings, below by the converging heads of the gastrocnemius. Most superficially is the internal popliteal nerve; the vein lies on the artery; the artery lies the deepest. The popliteal vein lies slightly to the outer side of the artery; whilst the internal popliteal nerve—which is first one inch external, and then on the artery—finally tends to the inner side. The artery rests on the femur, the posterior ligament of the knee-joint, and the popliteus fascia covering the popliteus muscle.

Ligation of the Artery in the Middle Third.—Lay the patient on the face or in

the three-quarter prone position. Make a perpendicular incision in the line of the vessel, having its central point opposite the knee. The incision should be three inches long at least. Cut through the skin and superficial fascia, avoiding the external saphenous vein; divide the popliteal fascia; clear away the fat with the director; pull outwards the internal popliteal nerve; open the vessel-sheath on its inner side, separate the vein, and pass the needle from without inwards.

Ligation of the Artery in the Upper Third is best done from the inner side of the thigh. Lay the patient on the back; place the limb as for ligation of the femoral; the surgeon is to assume also the same position relative to the limb. Make an incision three inches long just behind a line drawn upwards from the adductor tubercle; the lower end of the incision being on a level with the tubercle. Cut through skin and superficial fascia; avoid the internal saphenous vein and nerve, pulling them backwards; recognise the sartorius, and cut through the fascia along its anterior edge, to find the round tendon of the adductor magnus; clear the part, tying or twisting some branches of the anastomotica magna; pull back the sartorius, the gracilis, the semi-tendinosus and semi-membranosus, and, passing the director behind the adductor tendon, search amongst the fat, when the artery will be easily found. Pass the needle from before backwards, and apply the ligature as far as possible from any of its larger branches.

The popliteal artery can only require to be tied for wounds or rupture, involving possibly the knee-joint, and, under these circumstances, the operation must be more or less of a tentative nature, and be performed under the disadvantages of the popliteal space being filled with blood-clot, and the pulsation of the artery arrested.

JAMES CANTLIE.

POPLITEAL ARTERY, Wounds of the.—1. *Causes.*—Stabs and other wounds inflicted from without; ulceration of the artery by the pressure of a sequestrum of the femur, or by laceration during its extraction. The artery may be ruptured subcutaneously by severe blows, strains, or wrenches.

2. *Signs and Diagnosis.*—If there be an external wound or sinus there is profuse arterial hæmorrhage, the limb below becomes blanched and cold, and the pulse in the tibial arteries is greatly weakened or lost. Loss of tibial pulse indicates a very

free or complete division of the artery; if the tibial pulse be not affected, it shows that the hæmorrhage is from some branch and not from the main trunk. The signs of a subcutaneous rupture resemble those of a ruptured aneurism; there is a rapidly formed tense swelling in the ham, extending up the thigh and down the leg; coldness, pallor, and loss of pulsation in the arteries of the leg, which quickly becomes gangrenous. There may be a bruit in the swelling; signs of inflammation are wanting.

Treatment.—If all hæmorrhage has ceased when the surgeon sees the case, he should content himself with dressing the wound antiseptically, and with keeping the leg and foot slightly raised and at perfect rest, either fixed on a splint or resting between firm pillows. Where hæmorrhage is continuing, a tourniquet should be applied at once, and both ends of the artery sought and tied. For this it may be necessary to enlarge the wound, the incision being made parallel with the vessel, and great care taken not to injure the external saphenous vein and the popliteal vein and nerve; the artery lies very deeply, and the operation may prove exceptionally difficult. If the popliteal nerve is found severed, its ends should be united with fine catgut. If the vein be also wounded, it is a grave question whether amputation should not be at once performed; and if the wound be extensive, with contusion and laceration of the soft parts, or injury to the bone or joint, or the patient be old with a weak heart and diseased vessels, this would certainly be the better course. Should the patient be young and otherwise healthy, and the wound a clean incision and limited in extent, the vein should be ligatured as well as the artery; but if moist gangrene ensue, secondary amputation at the level of the wound will be necessary. In cases of necrosis of the femur, an attempt to tie the artery should be made, but if this be found impossible, amputation of the thigh should be at once performed. Should secondary hæmorrhage occur, an attempt to re-ligature the vessel should be made; failing this, amputation is indicated. In cases of rupture of the artery, an incision should be made along the outer edge of the semi-membranosus muscle, and search made for the ends of the vessel, which should be tied. The effused blood should, as far as possible, be allowed to escape, and the condition of the limb below be carefully watched. If signs of 'moist' gangrene appear in the foot and leg, amputation

through the lower third of the femur should be at once performed; where the gangrene is 'dry,' the separation of the sphacelus may be left to nature.

A. PEARCE GOULD.

POPLITEAL SPACE, Diagnosis of Affections of the.—The affections of the ham, requiring to be carefully distinguished from one another, may be grouped under the headings of *sinus* and *swellings*.

A *sinus* in the ham may be the sequel to a simple or a lymphatic abscess, or may be connected with necrosis of the lower end of the femur, or with disease of the knee-joint. To determine the question, the general outline of the joint and bones, the degree of mobility of the joint, and the history of the case must be made out, and the sinus should be carefully probed. Where there is no enlargement of the bones or joint, and the movement of the joint is painless and free from grating, and the probe fails to detect any bare bone, it may be regarded as a *simple sinus*. With a sinus present, the joint may be held flexed and complete extension be impossible, owing to contraction of the ham-strings and the matting together of the parts around the sinus. Unless the sinus be very carefully probed, a small surface of bare bone may be overlooked. If, however, the probe strike bare bone, the diagnosis of *necrosis* will be arrived at. Necrosis of the flat popliteal surface of the femur is very common, and when it occurs, no involucrum of new bone is formed around the sequestrum. Where, with a sinus, there are the usual signs of disease of the knee—swelling, rigidity, pain, grating in the joint—the dependence of the sinus upon the *arthritis* will be evident.

Swellings.—It is most important to determine whether any given swelling is connected with the popliteal artery or not, and no pains must be spared in this investigation. The chief sign of such connection is pulsation in the tumour. Pulsation may be due to one of three causes—(1) Contact of a tumour with the main artery; (2) extreme vascularity of a solid tumour; (3) communication with the artery—aneurism. (1) When the pulsation is communicated, it is heaving in character, and the tumour is not expanded with a wave; compression of the main vessel does not cause the tumour to shrink, and, except in the case of reducible bursal cysts, the tumour does not yield under compression. In the latter case, the tumour is reducible when the artery above is not compressed. In many

of these cases the pulsation is limited to or most intense in one part of the swelling, and can be increased by gentle pressure; it is often possible to draw the tumour away from the artery, and cause the pulsation to disappear. Such tumours have no thrill, and, if a bruit be heard, it is a dull thud rather than a prolonged blowing sound; the pulse in the artery beyond is not modified.

(2) When pulsation is due to the vascularity of a tumour, it is somewhat expansile in character; but, on controlling the artery above, the tumour is quite unaltered in size and consistence, and is incompressible; on removing the pressure above, the pulsation at once returns as before. Often other special signs characterise these tumours—thus the pulsation may occur at a distance from the main artery, or there may be 'egg-shell crackling' at some part of the tumour.

(3) When the pulsation is due to aneurism, it is always expansile in character, and is felt as a wave distending the tumour, and generally it is uniform in intensity throughout the tumour. On compressing the femoral artery, the tumour contracts somewhat, and by gentle compression it can be made to yield still more; then, when the pressure above is removed, the tumour is filled out again in two or three bounding beats. Such tumours generally are the seat of a prolonged blowing bruit, and often of a thrill. The pulse in the arteries below is delayed in time, and lessened in force and size as compared with that in the opposite leg. From pressure on the vein or nerve there are often cyanosis and oedema of the leg, and neuralgic pains in the foot and ankle. See **POPLITEAL ANEURISM**.

A. Sudden Swellings.—Where in a previously healthy man a deep tense swelling suddenly develops as a result of a blow, strain, or other injury, and the leg below is found pulseless, cold, swollen, and livid, with numbness gradually becoming complete, the diagnosis of *rupture of the popliteal artery* may be made. Should there have been some amount of swelling in the ham before, or the patient have been conscious of a beating in the part, or subject to neuralgic pains in the leg and foot; and especially if the patient be at or past middle life, and have atheromatous arteries and hypertrophy of the heart, it may be regarded as a *ruptured aneurism*.

B. Acute Swellings.—Should the swelling be deep in the ham, painful, tender, the touch firm, and without superficial oedema, and with only communicated pulsation, if any at all, it is a *bubo* or en-

larged popliteal gland. The detection on the heel or ankle of some source of infection would support this diagnosis. If the swelling be less well-defined, boggy or fluctuating, painful, tender, and the superficial tissues be cedematous and reddened, an *abscess* may be diagnosed. In this condition the joint will be semi-flexed, and any attempt to straighten it out will be painful, and resisted by the patient. There will be pyrexia, and perhaps a rigor or rigors, to confirm the diagnosis. An abscess may be combined with aneurism, or may open into the artery. The surgeon should therefore carefully examine for pulsation, thrill, bruit, and especially for compressibility of the tumour when the artery above is controlled, and for alterations in the tibial pulse. Only when he has ascertained the absence of *all* these phenomena, must he diagnose abscess pure and simple.

C. Chronic Swellings.—A soft, rounded, compressible swelling, immediately beneath the skin, which is continuous with the saphena vein in the leg, is a *varix*.

If the tumour be subcutaneous and loosely adherent to the skin, movable over the deep fascia, with a lobulated surface, and a defined, rounded smooth edge, it is a *lipoma*. A soft, ill-defined, lobulated swelling at the back of the knee, adherent to the skin, and immovable in the subcutaneous fascia, is of no pathological importance.

A tense, more or less globular fluctuating tumour, painless and not tender, without any signs of connection with the blood-vessels, unless it be transmitted pulsation, is a *bursa*. This form of tumour is often reducible into the joint, and is most tense and prominent when the joint is extended. A firm, solid tumour deep in the ham, movable over the artery, with doubtful transmitted pulsation, is an enlarged *lymphatic gland*.

A very hard tumour, growing slowly from the bone in a young person, is an *exostosis*. These tumours may be multiple; they may cause severe pain by pressure on a nerve. Occasionally an exostosis is broken off by violence.

A firm, steadily increasing tumour, fixed to the bone, or expanding the bone over it, perhaps varying in consistence in different parts, is a *sarcoma*. Such a tumour may exhibit pulsation from its great vascularity; it may attain a great size, and involve more of the femur or tibia than its popliteal surface.

A tumour over, and irremovable from, the artery, with expansile pulsation, blow-

ing bruit, and thrill, yielding to pressure when the artery above is compressed, and subsequently filling out with two or three bounding beats, is a *POPLITEAL ANEURISM*.

A. PEARCE GOULD.

PORRO'S OPERATION.—This is the Cæsarean section together with supra-vaginal amputation of the uterus and removal of the ovaries and tubes. It is indicated in the same cases in which the CÆSAREAN SECTION, LAPARO-ELYTROTOMY, or SYMPHYSIOTOMY (Sigault's operation) may be performed; and, besides avoiding certain special dangers pertaining to each of these procedures, has the further recommendation that the patient cannot again become pregnant and be exposed to the same risks a second time. Another great advantage, which it possesses over any of these alternative operations, is that it can be performed at a fixed time selected by the surgeon, without waiting for the actual commencement of labour.

The possibility of performing this operation, and thus lessening the danger of the Cæsarean section had at various times suggested itself to Cavallini, Michaëlis, and our countryman Blundell, who was so far in advance of his time in many of his thoughts and writings on abdominal surgery. Storer, of Boston, U.S., in 1869, was the first operator who actually performed the operation on a living woman, having been forced to remove the uterus to check the hæmorrhage during Cæsarean section; the presence of a large uterine fibro-cyst being the cause of the hæmorrhage. The patient survived sixty-eight hours.

To Porro, of Pavia, the credit belongs of having first performed Cæsarean section, with the intention of also amputating the uterus and its appendages. His operation was performed on May 21, 1876, and both mother and child survived.

In the *British Medical Journal*, January 26, 1884, Dr. Godson records a successful case in which the writer assisted him; and he gives very complete tables of all the cases which he could collect. A study of these tables shows that, though the maternal mortality of the operation has been very heavy, it compares favourably with that of the ordinary Cæsarean section.

Operation.—The bowel having been cleared by enema, and the bladder emptied by the catheter, the patient is laid on her back, with the arrangements which will be found described in detail in the article on OVARIOTOMY. An incision five inches long

is made through the linea alba, bleeding points are secured by pressure-forceps, and the peritoneum is carefully opened to the same extent as the skin-incision. The possible escape of any of the contents of the uterus into the peritoneum is guarded against by placing carbolised sponges in the peritoneum, between its parietal surface and the uterus, all round the space selected for incision. A small incision is then made in the uterine wall, and rapidly enlarged by tearing with the two index fingers (a modification suggested by the writer during Dr. Godson's operation); the child is then seized and extracted, and handed to an assistant, who ties and cuts the umbilical cord. As the operator removes the child, the chief assistant grasps the uterus and closes the uterine incision, covering it by a sponge; he at the same time slips one hand past the uterus into the pelvis, and grasps it firmly just above the vagina, including in his hand the broad ligaments on each side; all risk of any serious hæmorrhage is thus prevented. The upper margin of the bladder, at its reflection from the uterus, should now be defined by a catheter or a steel sound, introduced before commencing the operation, and the wire of Kœberlé's *serre-nœud* passed round so as to include the uterus just above the internal os, and both broad ligaments, with the contained appendages. The wire is first pulled as tight as possible with the special forceps, and its free end is passed twice round the catch on the *serre-nœud* central screw, and then twice round the whole stem of the instrument, which is then screwed up; a strong capped pin, like that described for hysterectomy, is passed through the right broad ligament, the uterus just above the wire, and the left broad ligament, and the cap is screwed on. The uterus, with the placenta left *in situ*, is then cut away. See UTERUS, Extirpation of the.

The sponges are then removed from the peritoneum, the anterior and posterior *cul-de-sacs* are sponged out, a flat sponge is placed over the intestines, and the pressure-forceps are removed from the edges of the incision. The sponges and forceps are carefully counted by the nurse or assistant. The *serre-nœud* is tightened if necessary, and the stump is fixed in the lower angle of the wound by a strong suture passed through the whole thickness of the abdominal wall and the edges of the peritoneum, so as to close the latter firmly round the stump without constriction. The remaining sutures are introduced, and the flat sponge removed. After the sutures are tied, and the upper

part of the wound dressed and strapped, dry carbolic gauze is carefully packed round the stump, and under the stem of the *serre-nœud* and the supporting pin. The wire is then again tightened if necessary, and the stump trimmed; a silk thread is run in and out round the cut edge of the broad ligament and uterine stump, and firmly tied. The stump is then lightly and carefully smeared with solid perchloride of iron, and covered with the usual dry carbolic gauze dressing and straps.

The after-treatment is exactly the same as after hysterectomy. Various modifications of the operation have been proposed, but they have nothing to recommend them. One, that of Müller, requires a brief notice.

He makes a longer incision, turns the uterus out entire, and surrounds its neck with an elastic ligature before opening it and removing the child, the object being to save risk of hæmorrhage and of fouling the peritoneum with the uterine contents. The great objection to this is that the child is often asphyxiated by the elastic ligature stopping the uterine circulation, and the fear of this must always hurry the operator while applying the ligature, incising the uterus, and extracting the child. Such hurry is always to be avoided; and the risks above referred to (hæmorrhage and fouling of the peritoneum) may be equally well obviated by the careful arrangement of sponges, by the tearing of the main part of the uterine opening, and by grasping the uterus in the pelvis as described above.

The long incision necessitated by the Müller modification, apart from the danger to the child, increases the shock, adds to the exposure of intestines, to the length of the operation, from the number of sutures required, and exposes the patient to increased risk of hernia from the long scar.

One of the great advantages of the Porro operation is that all proper arrangements as to skilled assistance, &c., can be made beforehand, and thus no difficulty should arise in carrying out each detail with precision and care.

Drainage should never be necessary after an operation carefully performed, when necessitated by contraction or deformity of the bony pelvis; but may in rare cases be required when a large adherent tumour has been removed along with the uterus. In such cases the operation may have to be modified in many ways, and it may even be necessary to adopt Schröder's intra-peritoneal method of amputating the uterus; but a detailed discussion of all such eventualities would occupy too much space in the

present article, and they only require the application of the rules laid down in the articles on OVARIOTOMY, and UTERUS, Extirpation of the.

J. KNOWSLEY THORNTON.

POSITION interests the surgeon in diagnosis and treatment. Position in bed is frequently suggestive of the constitutional state. A patient sleeping on the back, with hands clasped behind the head, or resting on the side, with open hand under the face or temple, is generally doing well. After injuries and operations in the abdomen, the position on the back with down-stretched legs is of good omen; so is lying on the side with sufferers from chest-lesions. In advanced cases of tetanus, the backward arched position of the body is pathognomonic; but, even in early trismus, the patient's complaint of slight stiffness about the jaws acquires special importance, if the chin project and the head be thrown a little backward. In serious cases generally, the patient's high or low position in bed indicates power or feebleness; and, in determining the nature of many injuries, the position of parts may be one of the most obvious signs—e.g. in dislocations of the lower jaw, of the shoulder, elbow, and hip; so also in fractures of the lower end of the radius, and just above the ankle. In diagnosing the presence of tumours or collections of fluid in the chest or abdomen, much valuable information is gained from the influence of varying positions of the body on palpation and percussion.

The diagnosis of many tumours and ulcers is largely determined by position. The scalp is the favourite seat of cystic, the trunk of fatty, tumours. The majority of herniæ are on the front of the abdomen, of aneurisms at the bends of joints. The almost invariable domain of varix is the lower half of the body; the upper half is the favourite one of scrofula. Ulcers are rare in the upper limbs, and their position on the lower is in a large measure diagnostic. They are usually varicose below, and syphilitic above, the middle of the leg.

The operating surgeon has to consider position in making incisions, so as to prevent deformity, pain, and tension, and favour drainage by natural declivity. In operating on the face and neck, it is best to follow the natural lines; on the hand and foot, to elect the dorsal aspect, whenever practicable, so as to avoid cicatrices on the surface exposed to pressure. A similar consideration should influence the surgeon in planning his incisions for amputations. Position is of the

first importance in exploring and operating in the natural passages, in the administration of anæsthetics, and in treating aneurism, dropsy, hæmorrhage, hernia, and spinal and uterine affections and displacements; also in restoring persons whose lives are endangered by asphyxia or faintness.

In the treatment of wounds and fractures, and generally of surgical conditions, position is a potent factor, regulating nervous, vascular, and muscular action, preventing congestion, facilitating coaptation, and, in direct measure, favouring repair, with a minimum of constitutional and local disturbance.

'An elevated position, of any part of the body which admits of being raised above the rest, has effects far beyond what are generally known on the circulation of the elevated part, and consequently on the heat, pain, and tumefaction which may have previously existed. If the hand be held up for a little time above the head, the pulse immediately becomes soft. The hand is soon after found to be pulseless and reduced in size. There is a feeling of lightness and coldness, which continues for some time after the hand has been taken down.' This very simple experiment, related by James Macartney in his *Treatise on Inflammation* (1838), is full of instruction and suggestiveness, as to the value of position in surgical therapeutics. A purple and swollen leg has been proved to decrease one inch in circumference, at the expiration of sixty seconds from the time that an assistant held the foot vertically above the pelvis, the skin at the same time becoming pale and the previously tense tissues flabby. As a contributory to rest, position is potent for good, all the more so if circumstances permit the application of equable pressure. As a general rule, that position is therapeutically the best which is most conducive to the patient's comfort. See PRESSURE; REST; SUSPENSION; WOUNDS, Treatment of. SAMPSON GAMGEE.

POULTICES are hot, moist, local applications, which may be employed solely on account of the heat and moisture which they possess, or less commonly as vehicles for some special therapeutic agent. The poultices recognised by the pharmacopœia may be classified as *emollient*, *sedative*, *stimulant*, and *disinfectant*.

Emollient poultices are made of linseed-meal, bread, or starch. Their therapeutic effects depend entirely upon the heat and moisture which they contain, and, so long as the skin to which they are applied is unbroken, they form very efficient applications. They relax the tissues, and so relieve the tensive pain of inflamed parts; they also, by virtue of their heat, stimulate the vital processes of those tissues which are not too much injured to respond, and thus either aid the resolution of inflammatory products or hasten their approach to the surface. These properties they share in common with fomentations, and with the above reservation—viz. that the surface to which they are applied be unbroken—they are equally efficacious. Poultices retain their heat longer than fomentations, unless special care be taken to prevent the cooling of the latter by surrounding them with cotton-wool. This property is a great recommendation in cases where the frequent renewal of a fomentation disturbs the patient a good deal, or where the regular attendance of a nurse cannot be obtained. If the skin be ulcerated or the seat of any open wound, a poultice is an objectionable application, as it very quickly becomes sour and favours putrefaction of the discharges from the wound. When a poultice is changed, small fragments are very commonly left in the folds of the skin, between the clefts of the fingers, and under the nails for days together, and these, together with the discharges with which they are mixed, become centres of decomposition. Linseed poultices often irritate a tender skin, and frequently cause an eruption of irritable papules, which are liable to develop into boils.

A linseed poultice is best made as follows: The basin used should be well scalded and about half-filled with boiling water; linseed-meal from which the oil has been expressed should be dredged into the water, whilst the mixture is vigorously stirred with a spatula until a soft and tenacious pulp is produced. The linseed should then be quickly and evenly spread on a piece of linen, so as to make a poultice about one-third of an inch thick; the edges of the

linseed should be trimmed off, and the borders of the linen should be turned up on to the face of the poultice; the surface of the poultice should be smeared with a little olive-oil, so as to prevent it sticking to the skin. The poultice should be quickly applied, and covered over with a layer of oil-silk, so as to prevent the evaporation of its moisture.

A linseed poultice is very close-textured and heavy, so it is important that it should not be made any thicker than is necessary to obtain its heat-retaining properties.

A bread poultice is more porous and consequently lighter than a linseed poultice, but it retains more moisture than the latter, and soddens the skin much more. To make a bread poultice, the crumb of a loaf two or three days old should be well powdered and dredged into a basin of boiling water, and well stirred up until a pulpy mass is produced; all superfluous moisture should be drained away, and the bread quickly spread on linen, and covered with a piece of muslin so as to prevent its falling to pieces.

Starch poultices are not much used. They retain their heat a long time, but they yield very little moisture. The starch should be first mixed up with a little cold water, and then boiling water should be well stirred in until the starch acquires a gelatinous consistence; the further steps in the preparation of a starch poultice resemble those described for the preparation of a linseed poultice.

Sedative poultices contain some substance which acts locally as a sedative. The only official poultice of this kind is made of conium. Two ounces of the extract of conium should be mixed with a pint of boiling water, and then sufficient linseed be added, in the way described above, until a poultice of the proper consistence is made. Other anodynes, such as the tinctures of opium or belladonna, may be added to poultices.

Stimulant poultices are made of powdered mustard, when a strong stimulant or counter-irritant effect is desired; but both yeast and carrot poultices are credited with slightly stimulant properties, and have been used as local applications to sluggish or sloughing wounds. The efficacy of yeast poultices is thought to depend on the carbonic acid which is slowly evolved during the process of fermentation. Mustard poultices are strong counter-irritants, and they cause much pain when applied to a tender skin; they are also liable to produce troublesome vesication if they are

apt on too long; as a rule they cannot be borne for more than twenty minutes.

Mustard poultices are employed to influence deep-seated inflammations, such as pneumonia or bronchitis; to stimulate a failing heart, or as a general stimulant in low fevers when stupor or delirium are present, or to rouse a patient from the stupor resulting from narcotic poisons. To make a mustard poultice, the powdered mustard should be well mixed with cold water, which should be added gradually until a thick paste is produced; hot water should on no account be used, as it causes the active principle of the mustard to evaporate. Vinegar, which has been recommended for making mustard poultices, is still more objectionable, as it destroys the active principle. The mustard paste should be spread on a piece of brown paper and warmed by a short exposure to a fire before it is applied, as the chill of a cold application might be objectionable.

When a mustard poultice is employed to modify a deep-seated inflammation, the poultice should be diluted with bread or linseed, and applied for five or six hours as a jacket-poultice to the entire chest.

The *disinfectant poultices* authorised by the pharmacopœia, are made of either charcoal or a solution of chlorate of soda mixed with linseed and water, but the oakum poultice is far better than either of these. Charcoal in a dry state is well known to absorb gases, but it is questionable whether it retains this power when its pores are filled with moisture, as must be the case in a poultice; it is also questionable whether it possesses any true disinfecting power at all. At the best, a charcoal poultice is an unsightly application, and is very inferior in its action to many modern antiseptics; it is far preferable to wrinkle the wound with crystals of iodoform, and to apply a fomentation over all, than to make use of a charcoal poultice.

To make a charcoal poultice, equal parts of animal charcoal and linseed-meal should be thoroughly mixed and dredged into a basin of boiling water, just as in making a simple linseed poultice.

The chlorate of soda poultice is composed of two ounces of the solution of chlorate of soda, four ounces of linseed meal, and eight ounces of water. It would, however, be far preferable to wash a foul ulcer frequently with the disinfectant than to apply it as a poultice.

The oakum poultice or fomentation is a very good antiseptic application; it is made of loosely picked oakum and pre-

pared, like a fomentation, by wringing it out of boiling water; it is well to wrap up the oakum in a piece of muslin before applying it to a wound, as its fibres are very liable to stick to the surface.

BILTON POLLARD

PRESBYOPIA.—This name is given to the optical defect of the eye which is caused by natural senile changes in the crystalline lens, in consequence of which changes the nearest point of distinct vision recedes from the eye. These changes consist chiefly of gradual hardening of the lens. This hardening process really goes on throughout life, with the result of causing a progressive diminution in the amplitude of accommodation, as the nearest point of vision recedes. The far point of distinct vision remains stationary until the age of fifty and then it also recedes, but more slowly than the near point, so that at the age of seventy-five the near and far points coincide—i.e. the amplitude of accommodation equals 0. When the near point has receded beyond 22 centimètres (about 9 inches) from the eye, which would correspond in a case of emmetropia to a remaining amplitude of accommodation equal to 4.50 dioptries, a difficulty is experienced in seeing small objects, such as small print, fine stitches, &c. This difficulty is first noticeable when the illumination is not good, e.g. during the evening, when artificial light is employed. It becomes necessary, under these circumstances, to supplement the existing amount of accommodation by means of a lens whose focal power, when added to one the focal distance of which equals the distance of the near point from the eye, is of sufficient strength to make that combination equivalent to a lens of 4.50 dioptries. In other words, we must place in front of the eye a lens which is sufficiently strong to bring the near point to 22 centimètres from the eye. Thus, for instance, if the near point be at 50 centimètres from the eye—i.e. equals the focal distance of a lens of 2.0 dioptries—it must be brought to 22 centimètres from the eye, which again equals the focal distance of a lens of 4.50 dioptries. The lens which will effect this has a refracting power equal to the difference between 4.50 and 2.0—i.e. equal to a lens of 2.50 dioptries.

Recourse will have to be taken to such aid sooner or later, and the actual glass required will have to be stronger or weaker according to the age at which the near point has receded beyond 22 centimètres from the eye. In hypermetropia this will

take place at an earlier age than in emmetropia, and earlier according to the degree of hypermetropia; in myopia, on the other hand, it will take place later than in emmetropia and later according to the degree of myopia. The condition of presbyopia is generally said to exist when such a glass is required as an aid to near vision, although more correctly it has begun when the same optical correction is not sufficient for both distant and near vision. The following table gives the number of the lens (in dioptries) generally required at different ages:—

Age		Age	
45 . .	1·00	65 . .	4·75
50 . .	2·00	70 . .	5·50
55 . .	3·00	75 . .	6·50
60 . .	4·00	80 . .	7·00

If the individual be ametropic and x represent the number in dioptries of the lens correcting his ametropia, x must be added to the lens given in the table for any particular age in the case of hypermetropia, and subtracted from that number in the case of myopia.

There are some special points which should be attended to in testing and prescribing glasses for presbyopia, viz.:—

1. The proper test to use, when the vision is good, is very small print (e.g. No. 1 Jaeger), as in order to read this there must be accurate fixation.

2. Care must be taken not to prescribe too strong glasses, as they are frequently resented, the reason probably being that the individual has always been accustomed to converge towards and accommodate for the same distance simultaneously; and as the defect in accommodative power is due to want of elasticity of the lens and not to weakness of the ciliary muscle, the correcting glass should not be stronger than the difference in the amount of accommodation which the contracted muscle actually effects, and that which it would bring about, did a sufficient elasticity in the lens exist. Any unwonted dissociation of the relation existing between accommodation and convergence gives rise in the long run to discomfort, which is the more felt the older the individual by whom the change has to be made.

3. Great care must also be taken that the two eyes are corrected for the same distance: this will generally be the case by the use of the same glasses, as the refraction is generally the same in both eyes, but it is a good precaution to test either eye separately. It is still a disputed point whether, in the interest of binocular vision,

each eye is capable of an independent amount of accommodation or not; in any case, it is pretty certain that, if such independence exist, it is only brought into play by more or less effort. If we do not bring the near point of both eyes to the same distance, we must have either defective or strained binocular vision. As long as there is a certain amplitude of accommodation left, there will also be a greater or less range through which the individual has distinct vision while using his glasses, as, although the eye provided with a convex glass has a smaller amplitude of accommodation than without, yet the diminution in the amplitude is but slight. Convex glasses magnify for two reasons—first, and principally, because they allow the individual to approach the object closer to the eye, but also because they cause the second nodal point of the eye to advance, and thereby increase the visual acuity; and this to a much greater extent than is done by the change in the crystalline lens, sufficient to give rise to an accommodation for the same distance.

G. A. BERRY.

PRESSURE.—As a cause of pathological states, a means of diagnosis, and a therapeutic power, pressure merits the closest attention of the surgical student and practitioner. It has been usual to divide the subject under 'compression' and 'pressure'; but these are essentially synonymous terms, only admitting of artificial distinction in science and practice. Pressure is the least ambiguous term, and its preference may, it is hoped, result in clearness of statement and economy of space.

As a cause of pain and functional disturbance in many constitutional states, and as the prime mover or concomitant in structural changes after injury, pressure operates variously, according to its intensity and duration and to the parts or tissues acted upon. In abscesses, cysts, and dropsies; in aneurisms and varix; after lesions of the nervous centres and of the thoracic and abdominal viscera; in atrophy and hypertrophy; contusions, dislocations, and fractures; in hernia and prolapsus; ulceration and gangrene—in fact, in the great majority of surgical states, pressure is an etiological factor deserving close investigation.

In the endeavour to determine if, and to what extent, pressure be the cause of pathological phenomena, accurate comparison of analogous parts of the body is very instructive. So, too, are measurement and palpation, auscultation and percussion:

in different positions, and examination of the organs of special sense and of the visceral cavities by instrumental aid. Light and deep tapping and grasping, dilating and concentric pressure, have distinctive diagnostic values; and the surgical student cannot be too assiduous in training his fingers to the exercise of intelligent pressure. The touch is scarcely more important to the pianist than to the surgeon: a proposition very forcibly demonstrated in the study of the therapeutic uses of pressure.

The coaptation of divided parts, the crushing and dispersion of a ganglion on the wrist, truss retention of a hernia, dilatation of strictures by bougies, injection of air or oil per rectum in cases of intussusception, are some of the most striking and varied illustrations of the mechanical action of pressure. Its other therapeutic uses, in combination with immobility and position, antiseptics and styptics, are *hæmostatic*, *antispasmodic*, and *antiphlogistic*.

In all methods for arresting hæmorrhage, by bandage, pad and tourniquet, pressure is the chief agency, to which physiological position and immobility are powerful contributors. The swelling which takes place immediately after a bruise or sprain is due to subcutaneous hæmorrhage, which is most efficiently controlled by uniform pressure and immobility. Nothing is more soothing to an injured joint, nothing more powerfully conducive to the balance of innervation and circulation, to the prevention of extravasation, and to its removal when it has taken place, than gentle, equable, elastic pressure. Much depends upon how, and with what materials, pressure is applied. If a limb be firmly bandaged with a strong calico roller, without padding, or over ordinary pads or dense common wadding, against wooden or iron splints, the risk is unquestionable; but perfect ease and safety may be ensured by applying pressure with light absorbent bandage, and absorbent gauze and cotton tissue, over well-fitting moulds. Pressure so applied is hæmostatic, anti-spasmodic, and antiphlogistic. Pressure is, by common mission, one of the most powerful therapeutic agencies in counteracting the effects of chronic inflammation; but its efficacy in preventing and treating acute inflammation, though equally demonstrable, is not generally known. No other triple combination in surgical therapeutics rivals in efficient power rest, position, and pressure. As to the degree of pressure to be applied, the patient's comfort must be the measure

in each case. Nothing in surgery is more noteworthy than the considerable amount of well-applied, equable, elastic pressure which may be borne, with the most perfect comfort, by a part just previously so sensitive that the slightest touch was intolerable.

When pressure causes pain, that is a proof of excess, and it should be at once lightened. It is misleading, and often dangerous, to wait for the relief of numbness which may succeed the patient's endurance of painful pressure. Such numbness may only indicate impaired vitality, and be the immediate precursor of structural disorganisation.

Well-adjusted elastic pressure is of great value in the treatment of such diverse conditions as simple flesh-wounds and complicated fractures, ingrowing toe-nail and burns, bubo, and carbuncle. Digital compression of arterial trunks is a powerful antiphlogistic, and gives relief, though often only auxiliary to other remedial measures, in whitlow and phlegmonous erysipelas, in arthritis and compound fracture. From the combination of equable elastic pressure of the surface, digital compression of the main artery, immobilisation of the joints and elevation of a limb, the most beneficial results may be anticipated in removing pathological products and restoring the physiological state.

Pressure may be applied in a great variety of ways. The most generally useful are bandaging with efficient padding or with india-rubber; strapping, adjustment of air- and water-cushions, or of bags filled with ice, sand, or shot. The pressure exercised by successive layers of freshly-applied collodion is considerable. Its antiphlogistic action is very beneficially demonstrated in the treatment of acutely swollen testicle, and it makes the best retentive and immobilising shield for fractures of the nose. *See POSITION; REST; WOUNDS, Treatment of.*

SAMPSON GAMGEE.

PROBANGS are instruments used to dislodge or extract foreign bodies from the œsophagus. The sponge probang consists of a long flexible piece of whalebone with a small sphere of sponge attached to one end; it is used to dislodge soft bodies, such as pieces of meat, which have become impacted in the lower part of the œsophagus, and to push them into the stomach. The horsehair probang is an ingeniously contrived instrument for extracting pins or fishbones from the gullet. The point of the instrument is protected by a small piece of sponge, and about an inch away

from it there is a wisp of horsehair, which can be made to open out something like an umbrella. After the instrument has been insinuated past the foreign body, the umbrella is made to spread out, and then the instrument is withdrawn, in the hope that the foreign body may become entangled in the meshes of the horsehair and so be removed.

An instrument known as a coin-catcher is usually combined with the sponge probang; it consists of a flat flexible piece of whalebone, at the extremity of which there is a metal ring, fixed at an acute angle with the whalebone. The best instrument is provided with two rings, which make an angle of about sixty degrees with one another, and are fixed by a hinge to the extremity of the probang; the hinge allows of one of the rings falling flat against the whalebone, if it meets with any obstruction as it is passed down the œsophagus. When the instrument is withdrawn, it is hoped that the coin may be caught by one of the rings and so be removed.

BILTON POLLARD.

PROCTITIS (Inflammation of the Rectum).—It is a symptom of many affections of the rectum, such as hæmorrhoids, polypus, prolapse, stricture, ulceration, &c., but may also occur independently of these, from local or general causes. It may be due to the introduction of foreign bodies into the rectum, or to the irritation caused by oxyurides, or to gonorrhœal infection. It may also be caused by large and repeated doses of drastic purgatives, or in some persons by errors of diet; or may be associated with diphtheria, gout, or constitutional syphilis. Gouty and diphtheritic proctitis come under the notice of physicians rather than surgeons. Constitutional syphilis sometimes appears to produce this condition. A young married lady who had lived for some years abroad, lately consulted the writer for a painful condition of the rectum, accompanied with a profuse purulent discharge which had persisted for six months. The sphincter muscles were firmly contracted, and the mucous membrane was hot and swollen. No breach of surface, piles, or other exciting cause could be discovered. As ordinary treatment for inflammation had previously failed, and as the history of the patient suggested the probability of some syphilitic taint, the writer prescribed five-grain doses of iodide of potassium thrice daily and a suppository of iodoform ointment to be inserted at bed-time. The painful sensations ceased

almost immediately, and the discharge gradually diminished, and finally disappeared in about three weeks.

Gonorrhœal inflammation may be caused directly by unnatural intercourse, or accidentally from a vaginal or urethral discharge. It is more frequently met with in females, as a vaginal discharge would, when the patient was in the supine position, gravitate towards the anus. The chances of rectal infection would be greatly increased by the existence of prolapse or piles. In males, the infecting material might be carried by the fingers of the patient to the anus. It is characterised by a profuse purulent discharge, and by burning and smarting sensations. The existence of a vaginal or urethral discharge, or a recent history of such, would indicate the cause.

Proctitis may be acute or chronic. In the *acute* form the patient experiences a sensation of weight and heat in the perineum, and pain in defæcation. The sphincter muscles are usually firmly contracted, and the mucous membrane is hot, dry, and congested. A few small flakes of brownish mucus usually adhere to the finger of the surgeon, when withdrawn after digital examination of the bowel. This stage is usually succeeded after a few days by the *chronic* form. The sphincters are not firmly contracted, and may sometimes have lost some of their contractile power. The mucous membrane is cedematous, and there is a discharge of either gelatinous lumps of mucus, or of a mucopurulent or purulent fluid. This may escape either during defæcation, or, if the orifice be patulous, constantly, and so excite irritation and excoriation of the adjacent cutaneous surfaces.

Treatment.—In the acute stage, leeches to the perineum and warm baths will give relief. When the spasmodic contraction of the sphincter has subsided, lukewarm injections with, in adults, some laudanum, will be of service. In the more chronic stage the discharge can be arrested by injections of alum or of weak solution of nitrate of silver. The diet must be simple and such as will not leave a bulky residue, and alcoholic stimulants must be prohibited. If the inflammation has been excited by worms or some constitutional taint, appropriate remedies must be employed as well as local treatment. JEREMIAH MCCARTHY.

PROLAPSUS ANI et RECTI.
Eversion of the mucous membrane of the anus or of all the constituent structures of the rectum through the anal orifice.

The mucous membrane of the anus and rectum is attached to the other structures of the bowel by very lax connective tissue, so as to admit of its adaptation to the varying calibre of the tube. It is normally slightly everted during defæcation, and withdrawn again at the conclusion of that process by fibres of the tunica mucosæ muscularis, which are considerably developed at this part of the alimentary canal.

In feeble, unhealthy children, from the irritation of diarrhoea, or of oxyurides in the rectum, or of a calculus in the bladder, the mucous membrane may be more largely everted, and require adventitious aid for its replacement. This may also occur in adults from the like causes, or from the training resulting from constipation, rectal or urethral stricture, or prostatic enlargement. Prolapsed piles and rectal stricture also tend to produce this eversion. This condition is termed *prolapsus ani*, to distinguish it from eversion of all the structures of the rectum, which is known as *prolapsus recti*. This latter condition may result from congenital or acquired want of tone in the sphincter, levatores ani, and recto-coccygei muscles. It sometimes occurs in young persons from some congenital defect in these muscles. In adults it may result from some acquired want of muscular tone, especially in women who have borne many children. A large rectal polypus would also tend to produce it. The everted bowel necessarily draws with it, in the male, the recto-vesical and, in the female, the recto-vaginal fold of peritoneum. If the protrusion be considerable, this fold may be drawn through the anal orifice and so form a hernial sac, into which a loop of intestine or some of the pelvic viscera might fall. If, from inflammation of the surrounding structures, or from contraction of the sphincter ani muscles, the neck of this sac should become constricted, strangulation of the contents of the sac might result, and form a serious complication. The prolapsed bowel forms a spherical or cylindrical mass, projecting in extreme cases many inches from the anus.

The symptoms vary with the degree and condition of the protrusion. There is always a disagreeable sensation as of some foreign body at the fundament, and there may be mucous, purulent, or sanguineous discharge. If the protruded part become inflamed and ulcerated, there is local pain and general feverishness. This is naturally greater in prolapsus recti, from the greater amount of protruded mucous surface and

vascular structures. If the protrusion be neglected, the submucous tissue will become loaded with leucocytes and inflammatory exudation, so that the replacement will be either difficult or impossible, and the continued exposure will tend to produce ulceration and increased inflammation; sometimes sloughing of the protrusion results. If it be complicated with a strangulated rectal hernia, the usual symptoms of this condition will be superadded, and the protrusion can be felt in the anterior wall of the prolapsed rectum.

The *diagnosis* does not present any difficulty. In ordinary prolapsus ani, the mucous membrane forms an annular uniform projection with central aperture. If it be caused by piles, the protrusion may not be uniform, and so the orifice may be eccentric. The condition is, however, very evident, and as the treatment will practically be the same as for the concomitant piles, the distinction is not of importance. Prolapsus recti may be confounded with protrusion of intussuscepted bowel through the anus. But in prolapsus recti the cutaneous surface will be either directly continuous with the upper part of the exposed mucous surface, or separated from it by a groove, of which the upper limit can readily be reached by the finger introduced along the projection through the anal orifice. In intussusception no such limit could be ascertained.

The *treatment* will vary with the condition of the part, and with the cause. The prolapsus ani should always be, if possible, reduced. In recent cases this is readily effected by pressure with a sponge. But if the protrusion be very congested, compression, with the interposition of some oiled lint, may be necessary, so as by squeezing out part of the blood and lymph to render the replacement possible. In young children, fright and pain may induce much resistance, which may be easily overcome by inverting the patient, and, if there be much spasm of the sphincter muscles, an anæsthetic should be administered. When reduction has been effected, the nates should be pressed together, and kept in that position by adhesive strapping. If the prolapse has been caused by some general irritation of the alimentary canal, a powder of rhubarb grs. iij. and carbonate of soda gr. j. will be useful. If there be oxyurides, the rectum should be washed out with an injection of salt and water, but as the rectal worms are only emigrants from the cæcum, some vermifuge should be also administered. A vesical calculus must be removed by lithotomy. Tonics and atten-

tion to diet will also be requisite. In children with a tendency to prolapsus ani, defæcation should always be performed in the supine position, and the child should not be allowed to sit during the process.

In adults, similar treatment must be employed, the prolapsus being reduced, and the exciting cause, so far as possible, removed. If the protrusion become inflamed and irreducible, rest in the recumbent posture, with the application of ice or warmth to the part, and opium either by the mouth or rectum, unless otherwise contra-indicated, will be necessary. When the acute symptoms have subsided, the protrusion, if it be still irreducible, must be removed by ligature or cautery in the manner described for internal hæmorrhoids. *See HÆMORRHOIDS.* When the exciting cause has been suitably treated, astringent injections may be of service, as well by checking the mucous catarrh, which usually exists, as by constricting the vessels of the part. The injections may be of oak-bark decoction or weak solutions of alum or tannic acid. They should not exceed three or four ounces, and should be administered at bed-time, so that they may be retained as long as possible. Sometimes, linear cauterisation of the anal mucous membrane is very beneficial. The actual cautery or nitric acid may be employed, and the number of lines of cauterisation must be regulated by the amount of the prolapse. The resulting cicatrization will contract the part so as to prevent any future prolapse. In more severe cases, portions of the mucous membrane may be excised in order to produce a similar result.

In prolapse of the rectum, all the symptoms of anal prolapse exist in an exaggerated degree. The bowel must be at once replaced if possible, and the patient should wear some artificial support for the part. Many contrivances have been devised for this purpose. Anal obturators only increase the evil which they are intended to remedy, and an elastic pad of suitable size, retained in position by a T-bandage, will probably be found to be the most effectual. The radical cure of this condition has been attempted in many ways. The simplest consists in excision of portions of the mucous membrane. For this purpose, the patient should be placed in the lithotomy position and anæsthetised. The operator should then take up a broad fold of mucous membrane at the side of the bowel with four-pronged forceps, and excise it with scissors curved on the flat. When all bleeding has been arrested, the lateral

margins of the divided mucous membrane should be united by interrupted sutures, and the operation repeated on the opposite side of the bowel, and, if necessary, also posteriorly. A morphia suppository should be then inserted into the rectum, and the patient kept in the horizontal posture until the wounds have healed. The patient should be carefully watched for several hours after the operation, as hæmorrhage may occur in the rectum to an alarming extent without any external evidence. If the patient become pale or faint, the rectum must be examined and, if there be hæmorrhage, the clot must be removed, and the bleeding vessel, if possible, ligatured. If this be impossible, solution of perchloride of iron should be applied, and the rectum plugged with pledgets of cotton-wool. This procedure is sometimes completely successful, but sometimes causes only partial relief. The general health must also be attended to, and the different preparations of strychnia may be given with benefit.

In neglected cases, the protrusion may be irreducible from chronic inflammation. Being exposed to injury or irritation, it may ulcerate or, if strangulated by contraction of the sphincter muscles, slough. If the removal of the projection by operation be considered advisable, the operator must remember that the weight of the mass draws down the bowel, which might, unless suitable precautions were employed, slip up out of reach when relieved of the weight. Well-waxed ligatures should therefore be passed through the projection a little above the line of excision, which can afterwards be used as sutures to unite the mucous and cutaneous surfaces. Drainage-tubes should be introduced between the sutures, to prevent the retention of any discharge, and the patient must be kept at rest until union has taken place. The possibility of a peritoneal sac must also be remembered, and careful digital examination made to ensure that it is empty. Prolapse of the rectum is, however, comparatively infrequent, and the hernial complication is very rare.

JEREMIAH MCCARTHY.

PROSTATE, Diseases of the.—**GENERAL VIEW.**—The prostate is a compound organ, being partly glandular, but chiefly muscular. The glandular portion secretes a fluid which lubricates the urethra prior to the venereal orgasm, and which also forms a part of the discharge emitted during the sexual act. The muscular portion assists in the expulsion of semen from

the urethra. The double function of the prostate being, therefore, sexual, its chief diseases are not met with before puberty. In the infant and child the prostate is very small; it is sometimes, although rarely, the seat of tumour or of the deposition of tubercle. After puberty, and up to fifty years of age, it is chiefly liable to inflammation and functional disturbance. It is not until after fifty that its liability to disease becomes of great importance, owing to its tendency to hypertrophy, and hence to cause difficulty in micturition. The prostate is seldom malformed; in extroversion of the bladder its anterior portion or roof is wanting, and if there is great lack of sexual and urinary development, the gland may be entirely absent. It is rarely wounded, except by the surgeon's knife in lithotomy, or by the improper use of catheters introduced through the urethra. It is very tolerant of injury, and little harm usually follows if the prostatic capsule remains intact. The average normal weight of the prostate is $4\frac{3}{4}$ drachms.

INFLAMMATION.—Acute inflammation is usually the result of gonorrhœa, and is most likely to occur if the patient has neglected himself, or has freely partaken of stimulants, or has used too strong urethral injections; but prostatitis may come on when every care has been taken in the treatment of the gonorrhœa, from its commencement. Other causes of prostatitis are, the application of caustic and other irritating solutions to the deep urethra, and the introduction of urethral instruments, particularly when very large or when roughly used. Severe stricture of the urethra, stone in the bladder, and prostatic calculi, are not infrequent causes. Sitting in a cold damp seat, especially when heated after exercise, excessive venereal excitement, and hard riding have all been known to cause this affection. Other causes, such as hæmorrhoids, ascarides, drastic purgatives, turpentine, cantharides and other medicines are often mentioned, but the evidence is unsatisfactory. A form of prostatitis, without very apparent cause, is not usually met with in middle-aged men who are habitually free livers; they may perhaps recently have been exposed to cold or damp, indulged in excessive venery, or been longer than usual in the saddle; but generally the attack cannot be definitely attributed to these causes. This condition has been called by some, not inappropriately, acute prostatitis.

Symptoms.—The most evident is an urgent, frequent, and painful desire to pass

water. The pain is not relieved by micturition, but rather aggravated by it. With the first flow of urine some muco-purulent matter passes, and with the last few drops a little blood may appear. There is usually considerable constitutional disturbance, and occasionally the demand for relief from pain is very urgent. Complete retention of urine sometimes occurs.

Prognosis.—The inflammation usually disappears, if actively treated. In some cases matter forms; this formation is often preceded by a definite rigor, and abscess is produced. In other cases the inflammation becomes chronic, with chronic pain and chronic urethral discharge.

Treatment.—Absolute rest must be enjoined, preferably in bed, but at least upon a couch. A hot sitz-bath should be taken twice or thrice daily, the bowels be freely opened, and doses of liq. potassæ (℞xx.-xxx.) in water administered every three or four hours, washed down by good barley water. The diet must be light, stimulants be forbidden, and, if gonorrhœa is present, urethral injections be abandoned. If the symptoms are severe, half-a-dozen leeches should be applied to the perineum, previously shaved and washed. As they fall off, bleeding should be encouraged by fomentations. If pain continues, an anodyne draught or suppository may be administered. Small doses of tartar emetic or of antimonial wine are often useful.

CHRONIC INFLAMMATION.—Acute inflammation may become chronic, which is characterised by painful and frequent micturition, sometimes by constant pain, and by the presence of a few muco-purulent shreds in the first flow of urine. Per rectum the prostate is found larger and harder than it should be, either symmetrically or on one side. Frequently, this condition is accompanied by sexual hypochondriasis, and the general health becomes seriously impaired. Sexual intercourse is often painful when the orgasm occurs.

Treatment.—A blister should be applied to the perineum, and kept open by a savin ointment dressing. A few cases are benefited by the careful introduction of a steel sound not larger than No. 11. Injections are useless. The general health must be maintained by cod-liver oil, iron, simple but nutritious food, and perhaps some sound red wine; a little blue pill, and an occasional dose of aperient salts, being given to those of full habit. Finally, as no organ can be healthy unless its function is regularly performed, the best and also most certain cure is a happy marriage.

ABSCCESS.—Acute prostatitis may run into abscess in from five to seven days. Pus may form in the follicles or in the parenchyma, or around the gland; or it may result from the breaking down of tubercular deposit, or from malignant growth or calculus in the prostate. Practically, suppuration in or about the prostate may be divided into acute and chronic abscess.

Symptoms.—In acute abscess all the symptoms of prostatitis are aggravated. There is always fever, and frequently a rigor. The difficulty in making water may increase until there is complete retention of urine. Chronic abscess generally comes on insidiously; it usually occurs in cases of prostatic hypertrophy, where catheterism is regularly practised. The patient has pain about the perineum, and is ill and complaining for some time before matter is detected. Prostatic abscess may spontaneously open into the urethra, rectum, bladder, or peritoneal cavity, or by the side of the anus, or forwards into the perineum. The writer has known prostatic abscess to fill one or both iliac fossæ, and to require opening in the groin like a bubo.

Diagnosis.—Fluctuation, in or about the prostate, is determined by a rectal examination with the finger. The operation is a painful one, and must be gently done, with the patient lying on his back and the finger well greased (not oiled). The swollen prostate will readily be defined. In chronic abscess, the prostate may appear only hypertrophied, and fluctuation may be difficult to make out.

Prognosis.—Acute abscess generally soon heals. Chronic abscess is much more serious, and not infrequently fatally exhausts the sufferer.

Treatment.—The soothing treatment of acute prostatitis must be vigorously carried out. Hot baths, poultices smeared with laudanum and belladonna, leeches, or wet cupping, a hot water enema and anodyne suppositories, may all be employed. Retention of urine must be relieved by catheter—if possible, by a soft one. Catheterism will often cause the abscess to burst into the prostatic urethra. No incision should be made until fluctuation is distinctly felt, unless the pain is so great that it seems desirable to relieve tension, for considerable thickening may undergo satisfactory resolution. Directly fluctuation is detected the abscess must be opened. If the matter is close to the rectum, it may be aspirated through the bowel or opened into the bowel with a small incision. If pointing towards the perineum or deeply seated, the surgeon

should pass his finger into the rectum and enter a sharp-pointed narrow bistoury into the perineum just in front of the anus; the knife will often have to pass in an inch or more before matter is reached. Tubercular, calculous, and ordinary chronic abscesses may sometimes require to be freely opened from the perineum and thoroughly cleared out and drained; in these cases a grooved staff should be introduced, and the patient held as for lithotomy.

URINARY FISTULA FOLLOWING PROSTATIC ABSCCESS.—After a prostatic abscess has been opened by the surgeon's knife, or has discharged spontaneously into the rectum, ischio-rectal fossa, or perineum, the case is not always at an end; for frequently, if it is not further treated, troublesome urinary fistula results, and great care will often be necessary to prevent this unfortunate consequence. The external opening of the abscess-cavity must be watched, in order to observe if any urine issues during the act of micturition. The patient's account must be verified by the surgeon's own inspection while water is being passed. If urine issues, the urethra must be examined for stricture, and if any is found, it must be treated immediately by internal urethrotomy or interrupted dilatation; for as long as stricture exists, so long will the fistula remain unhealed. If the urethra is found to be of normal calibre throughout, the case may be left to itself for a week or two and merely watched, in the hope that healing will take place naturally, the patient meanwhile keeping himself quiet. If, after this interval, the fistula has not closed, the patient must be taught to pass the simplest and softest catheter applicable to his particular urethra, and instructed to draw off all his water by catheter; not a drop of urine must be allowed to pass naturally, and, before going to stool, the bladder should invariably be emptied by the instrument. By these means the majority of cases will heal up soundly.

ATROPHY OF THE PROSTATE.—Exhausting disease like phthisis, the wasting of old age, the effects of pressure—notably in old-standing, unrelieved stricture—and diseases such as abscess in the prostate itself, will produce atrophy of that organ. There are no symptoms, and the affection is without clinical importance. A prostate is atrophied if it weighs between two and three drachms.

HYPERTROPHY OF THE PROSTATE.—After middle age the prostate is liable to undergo simple enlargement. This hypertrophy is singular because it is not the result of increased function, as it is in other organs.

such as the heart of the pregnant woman or the arm of the blacksmith; and it is important because of the great influence it frequently has upon the vital function of micturition. See PROSTATIC HYPERTROPHY.

PROSTATIC ULCERATION.—In old-standing urethral stricture, prostatic ulceration doubtless precedes extravasation of urine and prostatic fistulæ. It is not an independent disease, and does not require special treatment.

PROSTATIC 'STRICTURE.'—In the strict pathological sense of the term, prostatic stricture does not exist. Cases are met with occasionally, however, where the hypertrophy has so invaded the urethra that its dilatability is very slight, and the catheter goes so tightly that there is some excuse for speaking of 'stricture at the neck of the bladder.' A dilating olivary bougie or even metal dilator may be passed with caution, and the consequences watched before the operation is repeated; if irritation does not follow, some good may result; but, generally, the safest plan will be to select a catheter sufficiently small to pass with ease.

PROSTATORRHOEA consists of a thin mucopurulent discharge from the urethra, which is not easily distinguished from an ordinary gleet. It frequently supervenes upon a gleet, and occurs amongst those who are morbidly anxious about their sexual organs and who are in bad health. Sometimes the loss of fluid at stool is considerable. The patient always exaggerates the importance and severity of his symptoms.

Treatment.—Fresh air, exercise, tonics, sea-bathing, and liberal diet are chiefly indicated. The surgeon must assure the patient that the complaint is not a serious one, and insist upon his leading a healthy sexual life, which consists in the natural performance of the sexual function, never to be attained outside the pale of matrimony. The passage of a cold steel sound every three or four days may prove beneficial, but the best local application is a solution of nitrate of silver (5 to 10 grs. to f3j.) applied by means of a prostatic injector. A flying blister may often advantageously be kept up in the perineum for an indefinite period. When there is much loss of fluid at stool, it will be diminished if the patient is taught to use a small enema of water before retiring; the process of defæcation is then accomplished with little muscular exertion.

PROSTATIC NEURALGIA.—Men are sometimes met with who, having had many attacks of gonorrhœa or much urethral instrumentation, or being simply highly neurotic, complain of constant aching at

the neck of the bladder and along the urethra. They are free from all apparent disease of the prostate, the stream of urine from first to last is clear of inflammatory product, and there is no calculus or urethral stricture.

Treatment.—All the urinary and sexual functions must be regularly and naturally performed. The general health is to be attended to, and the hepatic system cleared by a few doses of blue-pill. Iron, nuxvomica, bromide of ammonium and, occasionally, belladonna will be found useful. As a rule, no instruments should be passed, but, occasionally, distinct improvement will follow the gentle use of a steel-sound. Perineal blisters may be tried.

TUBERCLE OF THE PROSTATE.—Tubercle rarely invades the prostate; and when it does, some other portion of the genito-urinary apparatus, generally the kidney or testicle, is always similarly affected. The deposit consists of grey miliary bodies in the glandular or stromal tissues; these coalesce, increase, and ultimately form bodies as large as a pea, or even a walnut; sometimes the whole gland becomes invaded. These tuberculous masses may at any time break down into abscess, which will usually burst into the urethra; but may open into the rectum, ischio-rectal fossa, or peritoneal cavity.

Symptoms.—Generally, the patient has frequency of passing water, and pain in the act. The finger introduced into the bowel may or may not detect the deposit, either as one or more isolated masses in the prostate, or as a general enlargement of that organ; for it is only after abscess has occurred, followed by destruction of tissue, cicatrization, and contraction, that the prostate can be said to become smaller when affected by this disease. The urine contains more or less pus, and occasionally a little blood. The patient slowly becomes weaker and thinner. The diagnosis is difficult, and can seldom be made except after considerable careful observation of the patient.

Treatment.—Urethral instruments must be avoided as far as possible. Stress is laid upon this, as these cases are often needlessly sounded for stone over and over again, with much injury. Abscess must be watched for and promptly treated, the patient's general health cared for by attention to diet, exercise, clothing, and climate, with the administration of such tonics as the individual case demands.

PROSTATIC CYSTS.—The prostatic gland follicles may become dilated and form

little cysts. These cavities are frequently found in the hypertrophied prostate. They may contain semi-fluid material or solid calculous matter. Hydatid cysts have not been found in the prostate, but they are not uncommon between the rectum and the bladder, and have been known to occasion complete retention.

PROSTATIC CALCULI.—Calculi may form in the prostate as in other glands, and must not be confounded with renal or vesical calculi, which may have become fixed in the prostatic urethra. They begin as inspissated prostatic secretion, with degenerated epithelium cells from the tubes and acini; irritation is caused, and phosphates are deposited. Several hundreds have been found in a single prostate. They vary in size from a pin's head to a pea; occasionally they grow as large as a chestnut, and a mass, consisting of coalesced calculi, has been removed weighing $3\frac{1}{2}$ ounces. When numerous, they may break through their partitions and collect in a kind of cyst; they then become faceted from constant friction. They consist of phosphate of lime, a trace of carbonate of lime, and animal matter (84.5 p.c.). They are frequently associated with other diseases of the urinary organs—namely, stone in the bladder, hypertrophy of the prostate, and stricture of the urethra.

Symptoms.—Prostatic calculi are often first detected when the patient is treated for stricture or for stone in the bladder. Here, the sound or the bougie conveys a grating sensation as it traverses the prostatic urethra, and, if the finger is introduced into the rectum, the stone may be felt through the prostate. In other cases the concretions may themselves cause local irritation, pain in sitting and moving about, possibly obstruction to the flow of urine, and sometimes even abscess.

Treatment.—The general treatment consists in attention to the health. The bowels and liver should be gently stimulated, and the mineral acids administered in an infusion of *alchemilla arvensis*, *buchu*, or *uva ursi*. The radical treatment consists in their removal by surgical operation. The formation may often be attacked per urethram with a short-beaked lithotrite, or a pair of urethral forceps or a curette; in using the latter two instruments, the calculus should be steadied by the left forefinger in the rectum. If the stone is large, an attempt may be made to seize it with the lithotrite, and push it backwards and upwards into the bladder, where it may be dealt with by lithotrixy. In other cases a

perineal incision must be made. The patient is anæsthetised, and placed in the ordinary lithotomy position. The formation is localised, and its size estimated by the finger in the rectum; a grooved staff is introduced and held in position. Generally a median incision will suffice, beginning about an inch and a half above the anus, and continued downwards for an inch and a quarter. The stone is cut down upon and removed with short forceps. Care must be taken that *all* the stone is removed. The bladder need not be interfered with by this operation, and it is usually a safe and simple one. After the operation, a soft catheter should be passed through the penis into the bladder, tied in, and worn for four or five days. If the stone is considered to be very large, the perineal incision may be made into the urethra upon a grooved staff, as in lateral lithotomy.

CANCER OF THE PROSTATE.—The nomenclature of tumours is in a transition state; according to the most recent classification, tumours of the prostate are divided into four groups: (1) Myoma, or new growth consisting entirely of muscular fibre, a very rare form of tumour; (2) adenoma, or simple hypertrophy, including the encapsuled tumours, *see* PROSTATIC HYPERTROPHY; and the two malignant groups, (3) sarcoma (encephaloid of the older nomenclature), the varieties of which are—(a) round-celled, (b) spindle-celled, (c) lympho-sarcoma; (4) carcinoma (*scirrhus*), the varieties of which are—(a) acinous, (b) tubular, (c) colloid. No case of epithelioma of the prostate is on record.

Under the head of cancer of the prostate we here include sarcoma and carcinoma. The former is much the more common. The prostate may be primarily or secondarily affected by cancer. Fortunately this distressing complaint is rare; it seldom attacks men in the prime of life, but is almost entirely confined to youth and old age.

Symptoms of Cancer.—A diagnosis of cancer must only be made after close watching of the case and careful consideration; for in ordinary hypertrophy there may be much pain, and great size and hardness felt by the rectum, so much so as readily to deceive the inexperienced. Moreover, chronic prostatic abscess, a much more common affection, may, in its earlier stages, and before it has declared itself by fluctuation or discharge of matter, present symptoms remarkably like those of cancer. The chief symptom is pain, more or less constant, described as about the neck of the

bladder, or at the end of the penis, or in the thigh or leg. At first there is frequency and difficulty in making water; generally the patient is more or less dependent upon the catheter. The urine contains, sooner or later, pus and blood. It may be noted here that the urine, in malignant diseases of the bladder, often possesses a peculiarly disagreeable smell, almost but not entirely characteristic to the practised observer. Washing out the bladder constantly, and with powerful disinfectants, may altogether fail to remove the odour. There are usually attacks of hæmorrhage. The patient becomes weaker and thinner, and latterly may have deposits in the glands of the groin, or in those along the course of the iliac vessels. In doubtful cases, the urine should be thoroughly searched by means of the microscope for cancer cells; it must, however, be remembered that the sources of error in such examinations are very numerous.

Treatment.—The patient's powers should be sustained by suitable food, stimulants and medicines; the bladder, if necessary, relieved of retained water by catheter exactly as in the retention from hypertrophy of the prostate, and washed out from time to time with disinfectants. Great care must be taken to ensure an easy daily opening of the bowels by suitable laxatives, such as senna electuary, aloetic preparations, castor-oil, or compound liquorice powder. The diet may be made to aid in this by the daily ingestion of whole-wheat meal bread, oatmeal, raw or cooked apples and other fruits (not too sweet), and green vegetables. The use of the enema, every day or every other day, will often prove of the greatest service. Above all, the patient must be relieved of pain: in many cases the hypodermic injection of morphia, combined with a little atropine, will be best. In others, anodyne suppositories are useful, although the action of suppositories is always more or less uncertain. A suppository should always be applied after the bowels have acted, because a constant source of uncertainty of action is, doubtless, the pushing of the suppository into a mass of feces. In other cases, relief must be obtained by opiates administered by the mouth; they must be selected carefully, and those chosen which are best borne by the individual patient. Many will take laudanum, Battley's solution, or the liq. morphiæ hydrochloratis well; others will do well with the solution of the bimeconate of morphia, and others with the old-fashioned black-drop. Extir-

pation of cancer of the prostate is only mentioned here that it may be condemned. It has been attempted two or three times, and has in each case been followed by the speedy death of the patient. In one instance the peritoneal cavity was found, after death, to have been opened.

G. BUCKSTON BROWNE.

PROSTATIC HYPERTROPHY consists in an increase of the normal elements of the organ. The normal elements are: (1) *stromal*, consisting of involuntary muscular fibre, connective tissue, and elastic tissue; (2) *glandular*, consisting of racemose glands, formed of basement membrane lined with columnar epithelium, and containing secreted matters. The hypertrophy may consist of an equal increase of stromal and glandular structure. This is rare; more usually the stromal are increased far more than the glandular elements. In very rare instances the glandular portion is in excess of the stromal. In addition, there is an interesting and surgically important form of hypertrophy—namely, a growth of both structures, but chiefly of the stromal, in the form of distinct tumours. These tumours are embedded in the body of the gland, or may form nearly separate outgrowths into the bladder. They are rarely found except when general enlargement of the prostate exists. They are the peculiar bodies which occasionally come away entire in the surgeon's forceps, during the performance of perineal lithotomy.

Hypertrophy of the prostate is never found in men under the age of fifty. It usually declares itself between fifty-five and sixty-five. Actual hypertrophy of the prostate exists in about thirty-four per cent. of men at and above sixty years of age, and there are manifest symptoms in about fifteen or sixteen per cent. (Thompson). If a prostate weighs more than seven drachms, it may be said to be hypertrophied. An hypertrophied prostate has been known to weigh ten ounces.

For surgical purposes the prostate may be divided into three parts, two lateral lobes and a posterior middle lobe; these three portions may undergo equal hypertrophy, or any one of them may become more developed than the remaining two. The enlargement of the middle lobe is perhaps the most important, because it interferes more with the performance of micturition than does lateral enlargement. A patient may have marked prostatic enlargement and yet have little or no difficulty in passing water; on the other hand,

he may have great difficulty, and indeed may be unable to make any water except by catheter, and the surgeon may be unable to detect any enlargement per rectum. In such a case the middle lobe is the only part enlarged. Care must always be taken not to confound hypertrophy of the prostate with inflammatory depositions in that organ. Men under fifty are often carelessly spoken of as having enlarged prostates, when really they are suffering from prostatitis, or in rare cases have special pathological formations in the organ.

Causes.—The consequences of the enlarged prostate are so serious that, naturally, all who have studied the subject, from the earliest times, have anxiously inquired why a certain number of elderly men are so afflicted. We are still, however, in the dark, and the truest answer is that we do not know the cause of hypertrophy of the prostate. It may, however, be definitely stated that the disease affects all sorts and conditions of men, and that those of full or gouty habit, especially if they are obliged to lead sedentary lives, are more prone to the complaint than others. It has, indeed, been called 'the judge's disease;' and certainly judges, magistrates, members of parliament, bankers, clerks, shoemakers, weavers, tailors, and coachmen form a large proportion of those afflicted.

Symptoms.—The enlargement of the prostate necessarily interferes with the mechanism of micturition, and the bladder finds difficulty in dealing with any undue accumulation of urine, as after sleep or after the taking of stimulating fluids. This is the explanation of what is usually the first symptom of hypertrophy—namely, that the patient finds, on rising in the morning, that he can only empty his bladder by repeated efforts, and that he is therefore called upon to make water frequently during dressing. Others find that they are disturbed twice or thrice in the night to pass water. Often, there are obscure aches and pains about the neck of the bladder. There may be a little undue straining at stool, with ill-defined but general uneasiness. In rarer cases there may be marked pressure-symptoms, such as pain down one or other great sciatic nerve. The patient may be troubled with erections of the penis; he may also notice that his stream of urine is poor, that it does not commence well, and that when once begun he has to make continued effort to keep it up. If the patient obtains no relief from art, his symptoms gradually increase in severity. Very commonly, he may suddenly be seized with complete retention of

urine; but if this is not the case he gradually fails to empty his bladder, the quantity of habitually retained urine slowly increases, and the calls to pass water become more and more frequent, especially at night; he begins to experience pain when the desire to micturate comes on, which is relieved by passing water, and is therefore unlike the pain of stone. Throughout the progress of the disease the urine may remain clear and acid, but without the intervention of urethral instruments cystitis may come on, and the urine become decomposed and loaded with mucus and the products of decomposition.

Sooner or later the patient begins unconsciously to wet his bed at night. This incontinence is rarely true 'incontinence of urine,' which term means that the bladder cannot hold any water at all. Prostatic enlargement, in very exceptional cases, may so open the neck of the bladder that the organ can only retain a very small quantity of urine; but the surgeon must always suspect a man, over fifty years of age, who complains that he cannot hold his water and that it is always coming from him, of having a bladder full of urine, the apparent incontinence being in reality the overflow from an habitually full or engorged bladder. Too much stress cannot be laid upon this, and surgeons may accept as an axiom that *an involuntary flow of urine indicates retention, not incontinence*. Remembrance of this will save many a patient from death, and many a practitioner from disgrace. At any time hæmorrhage may occur; the bleeding is rarely severe, and often relieves the bladder and prostate considerably. If from ignorance on the part of the patient, or from a mistaken dread of the catheter on the part of either patient or surgeon, a case of prostatic disease, causing the bladder to fail to empty itself, is left untreated by instruments, the progress of the case will be as given below; death being sometimes more speedily brought about by the intervention of a chill, or retention of urine or other disorder, making surgical interference with the urinary organs absolutely imperative at a time when they may prove themselves unable to bear the shock of operation, in consequence of long-standing urinary embarrassment.

At first the bladder undergoes some hypertrophy, and then becomes either simply dilated or sacculated, owing to the great pressure which has to be exerted in order to void urine. By hydrostatic law, this pressure is equally transmitted in all directions, and brought to bear upon every

portion of the bladder-wall. Sacculatation of the bladder results from the mucous membrane being gradually forced outwards between the muscular trabeculae. Sacculi are almost invariably multiform; their walls consist merely of mucous membrane, and, where the bladder is covered by serous membrane, of peritoneum also. In advanced disease, an attack of retention of urine or the application of violence may cause rupture of a sacculus either extra- or intra-peritoneally, with fatal result, especially in the latter instance. Clinically, sacculi of the bladder are interesting, as phosphatic calculi are apt to form in them. Urine never regurgitates from the bladder into the ureters, but, as urine is constantly passing from the kidneys into the ureters, and as they cannot readily convey their contents into the engorged and constantly contracting bladder, they gradually become dilated; the pelvis of the kidney shares in this dilatation, and the renal structure itself becomes diseased from the obstruction met with to the outflow of urine. Interstitial nephritis ensues, followed by abscess (surgical kidney), uræmia, coma, and death.

In all cases of suspected hypertrophy of the prostate, a rectal examination should be made. The patient lies on his back, and the surgeon gently introduces his forefinger. The finger should be familiar with the dimensions of the normal prostate, which is not larger than a chestnut, and can easily be defined above and on each side. Usually, the enlarged prostate will feel as large as a Tangerine orange, sometimes much larger. As before stated, occasionally no enlargement may be felt by rectum, although there is sufficient hypertrophy of the middle lobe to cause complete retention. In certain cases it is proper to ascertain the amount of prostatic growth into the bladder; but this can only be done by the introduction of a short beaked metal sound, and, as instrumentation should always, at the commencement of treatment, be reduced to a minimum, the prudent surgeon will rarely deem it necessary to sound unless symptoms of calculus are also present. When the prostate is examined by a sound, the length of sound introduced before the cavity of the bladder is reached must be noted, and, when the beak has fairly entered, an attempt should be made, by depressing and rotating the handle, to turn the beak to one or other side. If at the same time the finger is passed into the rectum, a very good idea can be formed of the extent of the hypertrophy. It has been asserted that the enlarged prostate grooves the feces as they

pass. This is not the case. Sometimes, owing to great hypertrophy of the prostate, the bladder becomes entirely an abdominal organ, and, when only containing five or six ounces of urine, suprapubic dulness on percussion will be found as high as the navel.

Treatment.—The importance of the treatment of enlarged prostate cannot be over-estimated. If properly treated, life may often be indefinitely prolonged instead of suddenly cut short, and the latter part of it rendered tolerable and useful instead of miserably painful. Moreover, there are few cases more likely to bring the surgeon into sometimes deserved, but far oftener into entirely undeserved, discredit. Thus, a surgeon overlooks a distended bladder, another practitioner passes a catheter and removes a pint or more of urine, to the great advantage of the patient, who naturally draws his own inference; or, on the other hand, from causes explained further on, a case may perish in spite of the most skilful attention after the passage of a catheter.

In the first place, it must be definitely stated that all attempts to diminish the bulk of the enlarged prostate by means of medicines applied locally or by the mouth; or to excise portions of the gland by perineal incisions, or by instruments introduced through the urethra, or to destroy portions by the electric or other cautery, are worse than useless. So also is the injection of iodine into the body of the gland, or the use of bellied sounds to dilate the prostatic urethra. Grave injury may be inflicted by all these attempts to make a radical cure, and although the subject is a very interesting one and has engaged the attention of many good surgeons, there is at present no sound evidence before the profession that any of these plans of treatment are of the smallest use; the practitioner may, therefore, safely dismiss them from his mind, and confine himself to the palliative treatment of the affection.

CATHETERISM.—When a patient, over fifty years of age, without any history of stricture, and unaccustomed to urethral instruments, consults his surgeon about frequency in passing water, and perhaps other painful urinary symptoms, it will be of the first importance to ascertain if he is emptying his bladder. This can only be done by passing a catheter, and, as will be immediately described, catheterism may be followed by important consequences. These consequences will be much less severe, and in many cases may be effectually warded off, if the following precautions are taken.

They should always be taken wherever easily practicable, and invariably if the patient has had urinary symptoms for some time, and if he is elderly, worn-out, and really ill. Other cases may be treated with a little less ceremony, and sometimes necessarily so, since nervous patients may be seriously excited and alarmed if they see that much preparation is required, and they may therefore be tempted to forego the operation and lose the chance that surgery offers them of maintenance of health. In such cases, the surgeon may pass the catheter in his consulting-room, but he will do well to advise his patient to go home immediately afterwards, and, if not very robust, to go to bed and stay there, warm and quiet, for the next twelve or eighteen hours. But if convenient, and certainly if the case appears to be a grave one, an appointment should be made with the patient to meet him in his bedroom at home; the room must be warm, and he should be in his dressing-gown, ready to go to bed if so advised, after the catheter has been introduced.

Before passing a catheter, the patient is desired to make all the water he can by his natural efforts; he must be at his ease, and on no account be hurried. He is then placed with his back to the wall, and the surgeon seats himself in front and passes a perfectly clean, small, soft catheter. A No. 7 E vulcanised india-rubber catheter is less painful to the patient than any other, but sometimes it will not pass readily, and then a soft *coudée* catheter of the same size should be used. (See *Prostatic Retention* under RETENTION OF URINE.) All urine drawn off will be water which the patient could not pass, or 'residual urine.' The patient should keep his room for the rest of the day and take a hot sitz-bath; if the quantity drawn off exceeds three or four ounces, he should go to bed. If the bladder is found empty, and if all is well on the following day, he may be allowed to go about as usual. But if he is found to retain only one or two ounces, the experiment above detailed should be repeated next day, in order to avoid error. A frequent source of error is that the patient, when desired to pass water, fails from nervousness to make his bladder act as fully as it is really capable of doing. If, however, several ounces are found retained, or if the habitual retention of two or three ounces is confirmed by a second inquiry, the patient will have to commence the regular use of the catheter, and will at first need close attention. Should the quantity of retained urine be considerable, say ten to twenty ounces, he must not be

allowed to leave his bed, and will require special treatment, which will be detailed after the fever which may follow catheterism has been described.

FEVER FOLLOWING CATHETERISM (Urinary Fever).—Some men take to the habitual use of the catheter without any constitutional disturbance; but, usually, catheterism is followed by a more or less well-marked febrile attack. This fever comes on independently of abrasion of urethral surface or of any septic contagion; it is frequently confounded with septicæmia, but is quite a distinct fever. It must not be forgotten, however, that septicæmia may follow injury to the urethra, just as it may follow a wound in any other part of the body. The fever now under consideration has unquestionably a neurotic cause, being due to reflex irritation communicated from the urethra to the excretory apparatus of the kidney; it may follow the most skilful and delicate passage of a urethral instrument with every antiseptic precaution, or any kind of surgical or other interference (passage of a renal calculus) with the urinary organs. The kidneys are in a state of shock more or less complete, and more or less temporary. The shock may be so profound that, for a time, there is complete suppression of urine. Practical surgeons have long been satisfied that the fever has a renal origin; the term *urinary fever* is, therefore, more correct than the terms catheter or urethral fever which are sometimes used.

The time that may elapse between catheterism and the onset of urinary fever is very uncertain; fever may come on within a few hours or any time during the first week. It is generally but not always marked at its outset by a rigor, followed by heat and profuse sweating: the temperature varies from 100° to 105° F. The attack may be very transient, or it may be recurrent; but it is usually a continuous fever. The patient feels very low and prostrate, the tongue becomes dry, there is no appetite, but great thirst. This condition may last a week or ten days and pass gradually away, or the patient's state may become rapidly alarming. If the temperature keeps high (108°) and the pulse for some days is over 100, and if the tongue is hard, dry, and furred, the prognosis is unfavourable. Usually, the temperature rapidly comes down, the pulse keeps about 90, and the patient ultimately makes a good recovery and remains thoroughly accustomed to his catheter. In the present state of our knowledge, there is reason to believe that these cases do not end fatally if the kidneys are healthy at the

outset, and if all the precautions about to be described are taken. But if, from long-standing urinary obstruction, the kidneys are diseased, they may not be able to recover themselves, and the patient dies uræmic and comatose.

Unfortunately, the use of the catheter appears to the patient and his friends to be the starting-point of the illness, and surgery, or in other words the catheter, is unjustly blamed; whereas the fatal result is really due to want of the catheter at the proper time. For, if that instrument had been used when the obstructive disease first manifested itself, the renal mischief which actually causes death would have been prevented. We have no means of ascertaining beforehand whether the kidneys are in a state to bear catheterism or not; although, undoubtedly, urine of a low specific gravity is an unfavourable sign. But we need not let this inability impede our practice, for if a catheter is necessary, on account of partial or complete retention, *it must be used*, otherwise the patient's fate is sealed; and if, through long-continued, although perhaps unobserved, disease, he succumb from urinary fever, it is very certain that had he not used the catheter he would have died also, and with much suffering. *See URETHRAL FEVER.*

Treatment at commencement of Habitual Catheterism.—If from the patient's symptoms, and the large area of hypogastric dulness on percussion, there is little doubt that the bladder contains a large quantity of urine (a pint or more), the fever, which is almost absolutely certain, in such a case, to follow catheterism, may be considerably controlled if a small dose of opium, laudanum, or morphia, is administered half an hour before the catheter is first used. In all cases, if there is much constitutional irritability, advantage will follow the administration, two or three times a day, of small doses of morphia. Should rigors occur, spirits must not be administered, but the patient should be wrapped up warmly in bed, hot bottles be put to his feet, and hot tea or other simple drink given to encourage perspiration. From a consideration of the pathology of urinary fever, it follows that, at the commencement of habitual catheterism, all the organs which are complementary in their action to that of the kidney—the lungs, liver, intestines, and notably the skin—should be kept active and in order. This can only be done by confining the patient for at least a fortnight to a warm room, and, if there is fever, to his bed. The diet should consist of bread, vegetables, soup, fish, game, and

chicken, with little if any butcher's meat, and no milk or cheese; spirits must, as a rule, be avoided, and as little wine given as the patient's previous habits will allow. The bowels and liver must be kept gently acting by some laxative medicine, combined with small doses of blue pill. Irritation and soreness of the parts must be met by hot baths.

Above all, the patient must be able to obtain relief by the catheter whenever necessary. As the secretion of urine varies in quantity from time to time during the twenty-four hours, he should not be dependent upon the periodical visits of his surgeon for relief by the catheter, but should learn to pass it himself or have a skilful attendant always at hand. If the quantity retained is about three ounces, the catheter must be passed morning and evening. If the quantity is more than three and less than six ounces, the instrument must be used three times in twenty-four hours; if the amount is much over six ounces, it will be required four times a day. Should no water be made naturally, the catheter must be used whenever the desire to micturate comes on. Patients often try to postpone the use of the catheter as long as possible, and look upon the instrument as a source of irritation. This is not the case, and it is better for them to pass the catheter even oftener than is really necessary than too seldom.

Special Care after Complete Retention. For the instrumental relief of retention from enlarged prostate, *see* RETENTION OF URINE.

All the details above enumerated as necessary when catheterism is commenced, are here more than ordinarily called for. If the patient prove to be one of the very few who, after such an attack, do not require to commence regular catheterism, because he recovers with complete control over his bladder, he should keep his bed for twenty-four hours, and his house for two or three days, and take a little calomel or blue-pill with some colocynth or rhubarb. If, on the other hand, as is almost sure to be the case, the regular use of the catheter is required, the patient should be kept in bed until the fever, which is to be expected within the first five or six days, has passed away. A catheter should not be tied in unless, owing to irregularity of the canal or false passages, constant catheterism is very difficult. A silver catheter should never be retained. If the amount of retention has been great, say 30 to 40 ounces, the bladder should not be emptied at the

first catheterism, but about 20 ounces be drawn off. Death from syncope has been known to follow the sudden emptying of a bladder under these circumstances, and, in all cases, such a proceeding increases the shock to the system, causes pain, and may provoke dangerous cystitis. Generally, it is wise to let four or five days pass before the bladder is entirely emptied. Early in the progress of such a case there may be a good deal of hæmorrhage into the bladder.

After complete prostatic retention, it is improbable, although not impossible, that the patient will recover the power of emptying his bladder. He may be fortunate enough to regain his power completely; but this is very rare, and if he regains power at all, it is more likely to be partial only. In any case, he should learn to pass a catheter without delay, either in order to use it habitually, or when seized with retention, which is very likely to recur. Patients are often most anxious to be treated for want of bladder power, but reliance must not be placed on drugs, although a little strychnia may be given. The general health and nutrition must be carefully attended to, and the bladder allowed all the relief from the catheter it requires. The catheter is a good friend to an atonied bladder, and its use allows the bladder any chance it has of recovering its tonicity, although the very reverse of this is often considered to be the case.

General Treatment of the Enlarged Prostate.—Cases of prostatic hypertrophy are not infrequently met with, where there is no habitual complete or incomplete retention of urine, but where the patient is subject to sudden attacks of what he calls 'stoppage of his water.' These are brought about in three ways: first, by the influence of strong emotion or excitement, as great or prolonged mental effort, anger, fear, or grief, which appear to withdraw nervous energy from an organ already in need of all it can possess, and bring about entire inability on its part for a time to expel its contents. Secondly, by mechanical closure of the prostatic urethra and neck of the bladder due to congestion, which may be caused by exposure to cold, constipation, venereal excitement, and prolonged sittings (railway journeys in the sitting posture, particularly if occupying many hours, and if the weather is cold, are very likely to bring on retention in these cases). Thirdly, by any cause which fills the bladder with more urine than it is able to cope with, diuretic medicines, excess of alcoholic or

other stimulating drinks, or failure on the part of the patient to give his bladder an opportunity of relief when it first demands it. The advice to be given to these patients is obvious: they must avoid mental excitement, exposure to cold, much stimulant, long railway journeys, and so on. Above all, they must be taught to use a simple catheter, so that, whenever and wherever seized with retention, they may be able at once easily and safely to relieve themselves.

The majority of sufferers from enlarged prostate, however, sooner or later require regular catheterism, and should be invariably taught to perform it for themselves. The best instrument for habitual use, undoubtedly, is the soft French *coudée* catheter (No. 7, E.); the end is permanently turned up, and in consequence avoids the irregularities of the floor of the prostatic urethra and passes easily into the bladder. Some patients prefer the vulcanised india-rubber catheter; but its interior is small and its walls are thick, and contact with oil causes it to swell and destroys its polished surface. The olivary catheter is rarely desirable when the prostate is enlarged, but the English gum catheter is not infrequently superior to all others. As a rule, silver catheters should not be used. Sometimes the most careful manipulation of the catheter will fail to empty the bladder. When this is the case, there is probably some sacculation of the bladder, or dilatation of the ureters, or large inter-ureteral ridge. The patient is to be advised not to keep pushing his catheter in and out, in search of a little more urine, beyond a minute or so, but to trust to washing out the bladder at stated times to keep it free from decomposing urine. Much manipulation of the catheter is very likely to cause orchitis.

Catheters must be kept scrupulously clean; they should be syringed through every now and then with a solution of carbolic acid (1 in 500). The best lubricant is fresh olive oil; if desired, a little carbolic acid may be added (1 in 40). Some prefer castor oil and others vaseline. It will add much to the patient's comfort if he is directed to draw back the foreskin once or twice a day and wash with soap and water, to dry the part thoroughly, and apply a little simple dusting powder with a puff before readjustment. Neglect of this precaution may result in inflammation, soreness and itching, from the constant manipulation and contact with urine and oil.

The diet should be light and unstimulating; food should be selected which tends to keep the bowels easily opened, such as vegetables, apples, and brown bread. The less stimulants are used the better. Exercise should be taken regularly. When once the catheter has been mastered, there is no reason why the patient should not resume his usual activity, and ride or even hunt. He should also return to his usual pursuits and the ordinary duties of society; examples are numerous of men, occupying active and responsible positions, who have practised catheterism fifteen, twenty, and even thirty years, and finally have died of complaints in no way connected with their urinary organs.

The whole of the medicinal treatment of the enlarged prostate consists in keeping the bowels gently opened. Patients instinctively discover that they are never so comfortable as when the bowels act easily. An enema is useful, and mild laxatives, such as senna electuary, castor oil, aloetic oil, or compound liquorice powder, may, if necessary, be taken habitually.

The skin should be kept in constant motion by means of hot water and soap applied once or twice a week, and daily rubbing with a stout flesh-brush. There is no real need for patients to seek a warm climate during the winter months, if they are careful to be warmly clothed from neck to heel in flannel underclothing. Exposure to cold need not be avoided if extra clothes are worn. Great risk is often run by wearing evening dress; if this cannot be avoided, a deficiency of external clothing must be made up by additional underclothes.

Washing out the Bladder.—In prostatic disease it is often necessary to wash the bladder out. The mucous membrane may require astringent applications, or the urine may be sacculated, and the catheter may be insufficient to entirely evacuate the bladder, which, if left behind habitually, deposits and deposits the triple phosphate of ammonia, lime, and magnesia; in such cases irrigation with disinfectant washes is indicated for.

The best apparatus to use is an india-rubber four-ounce injecting bottle, with a stopcock, or a Higginson's syringe apparatus fitted with a two-way tap, specially arranged by the writer, and known as his bladder-irrigator. In these instruments, the hand regulates the quantity of fluid and the force with which it is ejected. Many forms of apparatus have been devised, chiefly on the principle of the syphon, which, among other reasons, are

objectionable because the force with which the injection is made cannot be nicely regulated. No air must be allowed to enter the bladder, and not more than two or three ounces of warm fluid (100° F.) injected at a time, although that quantity may be thrown in over and over again if deemed necessary. For cleansing the bladder, a solution of carbolic acid (gr. $\frac{1}{2}$ to f3j.) is useful, or boracic acid (f3j. of the saturated solution to f3j.) may be used. Other disinfectants which may be tried are perchloride of mercury (gr. $\frac{1}{2}$ to f3j.), liquor pot. permanganatis (℥xij. to f3j.), Barff's boro-glyceride (℥xij. to f3j.), and also thymol and sanitas. A good soothing wash is composed of f3ss. of glycerine and gr. xv. of borax to each ounce of injection. Nitrate of silver (gr. $\frac{1}{4}$ or $\frac{1}{2}$ or $\frac{3}{4}$ to f3j.) often acts remarkably well on the inflamed vesical mucous membrane. The mildest solution just named should always be used at first; if well borne by the patient, the injection may gradually be made a little stronger. Acetate of lead (gr. j. to f3j.) makes a good injection, especially when there is cystitis with a tendency to deposition of phosphatic crystals. The glycerine of tannin (℥iv. to f3j.) or tincture of steel (℥v. to f3j.) make good astringent washes, and quinine (gr. j. to f3j.) has been much used as a germicide. Dilute nitric acid (℥j.-ij. to f3j.) and dilute phosphoric acid (℥ij.-iv. to f3j.) are recommended when there is a tendency to alkaline deposits.

Phosphatic deposits can here be barely alluded to. When small, they may be washed out through large catheters; when larger, they come within the province of the lithotritist. If a patient has pain after he has used his catheter, blood and mucus in his water, and pain when driving, a stone behind his enlarged prostate should always be suspected.

Treatment of Advanced Prostatic Disease when Life is in Danger from exhaustingly frequent Catheterism.—Cases of habitual catheterism are exceptionally met with where, as age advances, the bladder becomes intolerant of urine, and the patient is gradually driven to pass his catheter more frequently, until at last he lives only to do so, hourly or even oftener. This continual exertion, night and day, rapidly exhausts an elderly man, and, unless relieved, he dies miserably. The circumstances of the case make the presence of a stone in the bladder not unlikely, and the patient should first of all be carefully sounded. If no stone is found, and the case permit of a little delay, opiates may be

tried, with rest and hot bathing. A soft catheter may be tied in, but it rarely does any good, and often adds to the patient's sufferings. If, on the other hand, the necessity for relief is urgent, and if morphia in its various forms is not tolerated or fails to give substantial relief, the bladder must be opened and drained, and not allowed to act as a reservoir for a time, but only as a channel. Suprapubic incision into the bladder has been tried and found wanting, and there are grave objections to rectal tapping and subsequent drainage, to perineal cystotomy, and to tapping the bladder with trocar and canula through the perineum without incision—an old method recently revived.

The safest and best means of drainage is obtained by the old operation, called by the French '*la boutonnière périnéale*.' The patient is anæsthetised, a grooved staff is passed into the bladder, and he is tied up in the lithotomy position. An incision, an inch long, is made through the skin in the median line of the perineum, ending within three quarters of an inch of the anus. The operator's left forefinger in the rectum distinguishes the apex of the prostate and the groove in the staff. A narrow, straight, sharp-pointed bistoury is introduced at the lower part of the wound, back downwards, and carried in front of the rectum to the membranous urethra, which is opened upon the staff, care being taken not to wound the bulb. A narrow blunt gorget is passed along the staff into the bladder, the staff is withdrawn, and the right forefinger (the left is reserved for the rectum) passes along the gorget into the bladder and explores its cavity; if nothing abnormal, except an enlarged prostate, is found, an india-rubber tube is passed through the wound into the bladder, by means of which drainage is effected for ten to fourteen days. The tube may then be permanently removed. The wound soon heals, the patient returns to the use of his catheter, and finds that the intervals between the catheterisations are considerable, and that life is again tolerable.

HÆMORRHAGE FROM THE HYPERTROPHIED PROSTATE.—During the first two or three weeks of entire dependence upon the catheter, the urine may suddenly be found to contain much blood. The bleeding is probably from the walls of the bladder, and is due to the withdrawal from them of the pressure of retained urine. Patients, also, who are accustomed to the catheter may occasionally pass much blood; they have had difficulty in passing the instrument, or

familiarity has somewhat bred contempt and they have been rough or careless; the hæmorrhage here is from the prostate. In advanced prostatic hypertrophy the vein about the prostate become enlarged, and bleed freely when injured. 'Vesical hæmorrhoids' are sometimes spoken of; but a condition deserving such an appellation is extremely rare. Whether the blood is from the prostate or bladder, the appearance of the urine is the same: it is intimately mixed with blood, and, when it issues from the urethra, the beginning of the stream is as bloody as the end. The blood is of a peculiar rich purple colour, and, looked at in bulk, is almost black. The patient and his friends are seriously alarmed, but with careful management he usually recovers.

It may be well to mention here that, in hæmorrhage from a tumour of the bladder, the stream of urine as it issues from the penis is usually more bloody at the beginning, or at the finish, than it is in the middle of its flow; it is generally most bloody at the finish. There is also pain with a tumour of the bladder, specially at the end of making water; this is not so in the cases now under consideration. The urine may be very full of blood in cases of stone in the bladder, but only after the patient has taken an unaccustomed amount of exercise.

Treatment.—Absolute rest in the lying posture in bed must be ordered and enforced. The urine must be drawn by a soft, easy-going catheter, passed with care and skill. Metal catheters should not be used. From injury to the urethra, the catheter can only be introduced with difficulty, it may be tied in and plugged; when the patient wishes to relieve his bladder, he does not rise from his bed, but simply turns over on his side and withdraws the plug. The bladder should not be washed out. Clots of blood in the bladder may safely be left to the disintegrating action of the urine; they gradually break up and come away. Should clot, however, get into the eye of the catheter and interfere with its action, a little cold water may be injected through the instrument and the clot washed back into the bladder. If, as sometimes happens, clots cause much difficulty, the catheter may be fitted with an English gum bougie just large enough to fill the interior; when introduced into the bladder, the bougie is withdrawn, and usually urine flows freely. In one case of the writer's, he and the patient were worn out by incessant trouble from difficult catheterism and the constancy

locking up of the catheter by clot. Morphia was administered freely, and under its influence the bladder was allowed to fill with blood and urine. In twelve hours the catheter was used cautiously. The patient was still kept under the influence of morphia, and the catheter used every six hours. At the end of forty-eight hours the urine came away almost clear, with quantities of broken-down blood-clot, and the patient made a good recovery.

Ice may be applied above the pubes or placed in the rectum, but it is of questionable service. An iced infusion of matico has been injected into the bladder, and in certain cases is worthy of trial. Styptics may be administered by the mouth: gallic acid, tannic acid, alum, iron alum, sulphate of iron, tincture of steel, red gum, hamamelis, Spasmodic's styptic and ergot are those generally used, but the writer has no confidence in these remedies. He considers opium, or some preparation of opium, the only medicine likely to be of service by the mouth. The system must be supported by light, nutritious foods; hot drinks should not be taken, and alcoholic stimulants are to be avoided unless the patient is much exhausted. G. BUCKSTON BROWNE.

PRURIGO is a chronic inflammatory disease of the skin, characterised by the formation of pale, discrete papules, accompanied by intense itching.

Cause.—Numerous theories have been advanced to account for the presence of prurigo, but none are satisfactory. Although it may be accompanied by diathetic conditions—scrofula, rachitis, &c., or by albuminuria, yet no one of these has been proved to be its cause. It is at present rather regarded as a disease of the skin itself. Prurigo, though a rare disease, is comparatively common in Austria, where it was first described, but less common in other countries; it is found most frequently amongst the poor, ill-cared-for classes. Though not confined to the genital, it makes its appearance very early in life (during infancy), at which period it is evidenced rather by the formation of wheals than of the peculiar papules now to be described. The disease is worse in winter than in summer, and generally persists during a lifetime.

Pathology.—There are two theories as to the pathology of prurigo. (1) That it is a neurosis, giving rise to a tetanic contraction of the arrectores pilorum, thus causing a papulation analogous to cutis anserina. (2) That it is inflammatory in origin. A considerable number of observations have

been made upon the prurigo papule, and there is pretty general agreement that the microscopic appearances are not peculiar, but such as may be encountered in any cutaneous inflammation—that is to say, there is cell-infiltration, especially in the papillary body, together with later changes in the epidermis, notably the exudation of fluid in the form of an abortive vesicle. It is this late formation of fluid which is said to give rise to the itching by irritation of the nerve-endings, the itching being always secondary to the papulation. What originates the inflammatory papules is not known. All other objective symptoms of prurigo are due to the mechanical irritation of the skin by scratching.

Symptoms.—The papules which are peculiar to the disease are often recognised with difficulty, as they are but slightly raised, and may be only perceptible to touch. In colour they may be pale red, but more often they take the hue of the surrounding skin; they are mostly of the size of hemp-seeds, and are not closely placed, but disseminated. The intense itching and consequent scratching which they give rise to soon modifies their appearance; their summits become abraded by the finger-nails, and ultimately topped with a minute blood or serum crust. Again, the scratching gives rise to the formation of other secondary blood-crusts, such as are common to all itching skin-affections. A picture made up of these disseminated blood-crusts, affecting especially the outsides and extensor surfaces of the limbs, the trunk to a less extent, and possibly the cheeks and lower jaw, together with a dusky, harsh, ill-nourished skin, is the one which is most often encountered in this country as the representative of prurigo (*prurigo mitis*).

In severer types of the disease (*Hebra's prurigo*, *prurigo ferox*), in consequence of the chronic inflammation the skin becomes deeply pigmented, the natural furrows deepened and exaggerated, especially in the neighbourhood of joints; finally, thickened and resisting to the touch, so that a fold is pinched up with difficulty. On passing the hand over the affected skin, say of the leg, it feels wooden and rough, like a coarse nutmeg-grater; this roughness is conferred by the broken wiry hairs which cover the part. The limbs are always the parts most affected, and of these the extensor surfaces. The flexures and scalp are very rarely attacked; the palms and soles, penis and scrotum, never. Prurigo of any grade, but especially the severer type, is liable to be complicated by linear excoriations, ecthymatous lesions,

and local impetiginous eczemas of varying extent and degree.

Diagnosis — from Scabies.— The long chronic history, the absence of burrows or lesions on the palms, soles, or penis; the absence of the eruption from the axillæ and insides of thighs, the presence of the eruption on the face, are the most important points. *From Phthiriasis or Pediculosis.*— The presence of the eruption about the hands; its characteristic localisation on the extensor surfaces rather than in the positions where the clothing fits tightly—e.g. the shoulders and waistband, as in phthiriasis; the absence of pediculi or nits about the clothing, which are rarely absent in old-standing phthiriasis. *From Eczema.*— Chronic eczema tends to affect the flexures; the scalp, penis, and scrotum are also liable to be the seat of the disease. Anatomically, eczema is characterised by closely set papules turning into vesicles. Many cases of prurigo are, however, complicated with eczema, only revealing their nature on the latter affection being cured. Prurigo must not be confounded with pruritus.

Treatment.— Tonics may be given if required—iron, arsenic, cod-liver oil. But only external remedies will give relief for any time; of these, soft-soap, sulphur, and tar are the best.

The uppermost layers of the cuticle should be removed by soft-soap baths, their use being alternated by the inunction of some bland oil (olive or almond). Then, after the irritation produced by the soft-soap has subsided, the patient should have the affected parts painted with juniper tar (ol. cadinum or *huile de cade*), and immediately afterwards he is to remain in a warm bath from three to six hours. Such treatment will mitigate the disease, and may be undertaken from time to time; but permanent benefit is not to be expected. Any complicating eczema should be controlled before the above treatment is undertaken.

A. SANGSTER.

PRURITUS. See PRURIGO.

PRURITUS ANI.—A sensation of itching on the cutaneous surface surrounding the anus. It is frequently most distressing, and local examination should always be made, as it sometimes depends on easily removable causes. The effects of scratching, which the itching induces, must not be mistaken for the cause. It is sometimes due to pediculi pubis which have, unknown to the patient, settled there. External piles and inattention to cleanli-

ness will also induce it. In fat subjects, chafing of the nates and retention of the secretion of the anal glands may cause it. Oxyurides in the rectum, or a chronic mucous or purulent discharge from the rectum, due to catarrh or piles, prolapse, polypus, or stricture, may be the exciting cause. Venous congestion of the part, from obstruction of the portal or systemic circulation or chronic constipation, may lead to malnutrition of the tissues, which may be expressed by local irritation similar to that experienced by patients with varicose veins of the lower extremities. This variety may be exacerbated by indulgence in alcoholic stimulants or by highly seasoned food. It is sometimes a symptom of gout. Occasionally, no cause can be discovered.

The *treatment* consists in the removal or alleviation of the exciting cause if it can be discovered. For pediculi, a lotion of corrosive sublimate four grains, rectified spirit two drachms, and water to an ounce will suffice. Oxyurides may be removed by injections of salt and water, with scammony and calomel pills. External piles should be cut off. Attention to diet and purgation will relieve local congestion. Perfect cleanliness is essential. Eczema will usually yield to some mild stimulating ointment, such as nitrate of mercury ointment, diluted with two parts of vaseline. When the itching has continued for some length of time, the skin will be found to be seamed with cicatrices produced by scratching, and the subcutaneous tissue will be converted into an unyielding mass by infiltration with leucocytes and chronic inflammatory exudation. In this condition, painting the surface with acetic acid—so that the acid shall not touch the margin of the anus—and the subsequent application of petroleum ointment, will be found very beneficial. This affection is especially intractable when the exciting cause cannot be ascertained. It is then probably due to some disordered condition of the constituents of the central nervous system. Internal administration of bromide and iodide of potassium may be advantageously combined with local applications. When the irritation is the result of catarrhal discharge, the exciting cause must be suitably treated. JEREMIAH MCCARTHY.

PSAMMOMA. See SARCOMA.

PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS.—Pseudo-hypertrophic paralysis is a progressive disease, characterised by weakness of many muscles, some of which are usually at first enlarged

and others wasted. The change in the muscles consists in an interstitial growth of fibrous and fatty tissue. Ultimately contractures occur, causing deformities. The affection usually commences in childhood, develops with growth, and after the symptoms have existed for ten or fifteen years, death occurs in consequence of secondary results of the weakness of the respiratory muscles.

The chief features of the malady were described in 1861 by Duchenne, who gave it the name by which it is now known, based on the muscular enlargement, which is, however, a variable and inconstant feature. A well-marked group of cases had been studied and described by Meryon in 1852, and isolated examples had been before published, the first by Sir Charles Bell in 1830.

Etiology.—Males are more prone to suffer than females, in the proportion of 1 to 1. The disease is often hereditary, and cases may occur through several generations. It is almost always inherited through the mother, who does not herself suffer from it. A woman's sons by different husbands may be affected. In other instances, several brothers and sisters may suffer, although in antecedent cases can be traced. Eight brothers have been known to suffer without any ancestral cases. The disease must, then, be due to a congenital tendency, although it is not actually inherited. In other cases, which constitute about half the total number, the disease is isolated, no other instance being traceable in the family. No hereditary relation to other diseases can be traced. The affection always commences during the period of development, and usually when muscular development is most active—in early childhood. In a few instances, symptoms have not been noticed until early adult life; but the disease always long precedes its symptoms, and in such cases there is often a history of large muscles since childhood, although there was no obtrusive weakness during youth. No immediate causes can be traced. Some morbid influences, such as acute diseases, have preceded the first symptoms, but have merely served, by their depressing action, to bring out the indications of the pre-existing malady.

Pathological Anatomy.—The affected muscles, whether large or small, are firmer than normal, unless the enlargement is considerable, and then they may be soft. On section they are yellowish in colour, and the much enlarged may resemble perfectly fatty tumour, no red tint being perceptible. The microscope shows that the resemblance

is more than one of appearance. The chief part of the bulk of the enlarged muscle consists of fat-holding cells, with fibrous tissue between them, identical in structure with ordinary adipose tissue. Here and there among the fat are bundles of muscular fibres, most of which are unduly narrow, although otherwise normal in aspect. Some, however, present signs of degeneration, and there are many empty sarcolemma sheaths, showing where fibres have perished. In the muscles that are small there is little fat; the fibrous tissue is increased, and the muscular fibres are narrow and in process of destruction. No other organ constantly presents changes. The spinal cord may be perfectly healthy; in some cases slight alterations have been found in it, but these have varied much in seat and character, and are certainly of secondary origin.

Symptoms.—These are of two kinds—the weakness of certain muscles, and the change in their size—both being the result of the morbid process just described. The increase in size, in rare cases, affects almost all the muscles of the trunk and limbs; usually it affects only a few muscles. Those almost constantly enlarged are the calf muscles and the *infraspinati*; next in frequency are the extensors of the thigh, *glutei*, erectors of the spine, *deltoid*, and *triceps*; much less frequently the *biceps* and the forearm muscles; very rarely the *masseters* are enlarged. The muscles almost always wasted are those that depress the raised arm—the *latissimus dorsi* and the lower part of the *pectoralis major*; they may even seem absent. The upper arm muscles may also be small instead of large. The extensors of the knee are frequently lessened in size. Sometimes, the *rectus* is small and the *vasti* abnormally large. Before definite muscular weakness is observed, often soon after a child learns to walk, a certain clumsiness of movement attracts attention; he readily falls, and runs with difficulty, and with a waddling gait.

The definite loss of power, which slowly comes on, affects, first and chiefly, the extensors and flexors of the hip and the extensors of the knee, and causes a characteristic defect of movement. There is a difficulty in going upstairs and in rising from the floor. If the child cannot take hold of furniture to help him up, he puts his hands on his knees, and so helps their extension by transferring part of the weight of the trunk from the upper to the lower end of the femur, close to the fulcrum of the lever which this bone then constitutes, and the part of the body in front of the

centre of gravity serves to aid instead of opposing the extension of the knee. If the extension of the hip is feeble, this movement is aided by grasping the thighs and moving the hands alternately higher and higher, and so, as it were, pushing the trunk up by 'climbing up the thighs.' Sometimes the extension of the knees is effected by getting on 'all fours,' and, when the child is resting on the toes and hands, the latter are transferred to the knees, first one and then the other, and the erection completed as above described. Lordosis is very constant, the lumbar spine being curved (convexity forwards) so as to cause a considerable hollow in the back, and the shoulders are carried backwards to compensate and maintain equilibrium. The lordosis is not the result of any weakness of the trunk muscles, but of that of the extensors of the hips, which causes the pelvis to be tilted forwards. When the patient sits, and the pelvis becomes horizontal, the lordosis disappears at once. Sensation, cutaneous reflex action, and the sphincters are all normal. The knee-jerk, however, is lessened, and ultimately lost. Slight contracture comes on in the muscles of the calf, so that the foot cannot be flexed beyond a right angle. There is, for a long time, little impairment of power in the arms. The mind is unaffected as a rule, although the disease has occurred in association with idiocy.

The loss of power slowly increases, until the patient becomes unable to mount a single step or to rise from the floor without help. He can still walk on level ground, swaying the body so as to throw its weight on to the leg that is on the ground. The contraction in the calf muscles increases until definite talipes equinus results, and at last prevents walking. When this occurs, the deformity rapidly develops, the foot becomes inverted, and the equino-varus extremely marked. The hamstrings also undergo contraction, and, in the sitting posture, the unequal weakness of the spinal muscles leads to lateral curvature. The arms gradually lose power, chiefly in the muscles of the shoulder and elbow; the hands remaining useful to the last. As the disease progresses the muscles waste, the fat becomes absorbed, the muscular fibres perish, and the fibrous tissue contracts. There is at first no change in their electric irritability; but, as the disease progresses, this irritability lessens slightly to both currents. Death results in most cases from chronic broncho-pneumonia, the result of the weakness of the respiratory muscles, or from some pulmonary or laryngeal inflam-

mation which that weakness renders serious. The course of the disease varies much in rapidity, and, as a rule, is shorter the earlier the symptoms begin. If it commences in early childhood, power of rising from the floor is lost at about eight, that of standing at ten or twelve, and death occurs between fourteen and eighteen. If the first symptoms are delayed till six or eight, the power of walking may not be lost till fourteen or fifteen, and life may be prolonged until twenty or twenty-two. In rare cases, failure of power does not occur until the end of the second decade, although enlargement of muscles has existed since childhood. In these cases the progress of the disease is slow, and may even cease.

The enlargement of the muscles, although a common and obtrusive characteristic, is not an essential feature of the disease. It depends on the growth of fat in the interstitial fibrous tissue: the latter may form alone, and all the muscles may be lessened in size, although firmer than normal.

Pathology.—The balance of evidence is strongly opposed to the idea that the disease is primarily one of the nervous system. Its origin, course, and character all suggest that it is a developmental disease of the muscles, the expression and result of a morbid tendency of growth, a vice of the germinal material, by which there occurs an undue development of the interstitial tissue, before which the muscular fibres waste. The weakness is due to the interference with the latter, and is thus a secondary effect of the overgrowth. The muscular fibres, moreover, seem to suffer less when there is a deposit of fat in the interstitial tissue than when this consists only in a fibrous overgrowth. The only symptom that might suggest a doubt as to the purely muscular nature of the disease is the loss of the knee-jerk; but that difficulty disappears if we regard this phenomenon—as the writer believes we must regard it—as the expression of a muscle-reflex irritability which may well be impaired by a muscular disease.

Diagnosis.—The diagnosis rests on the peculiar impairment of motor power, coupled with the enlargement of some, and the wasting of other, muscles. The enlargement of the calf muscles, with a contracture that cannot be overcome, the enlargement of the infraspinati, and the wasting of the depressors of the arm, the swaying walk and waddling run, the mode of rising from the floor, the lordosis, and the diminished knee-jerk, make up a characteristic group of symptoms. The chief diagnostic difficulty is the distinction from

ases of slight congenital spastic paraplegia, in which the muscles of the legs are large and firm, there is contracture of the calves, and the gait may resemble that of pseudo-hypertrophic paralysis. But attention to the following characteristics of these cases will always prevent error: The knee-jerk is excessive; there is a tendency to rigidity in the legs; the contracture of the calf muscles is active, and can be overcome by steady pressure applied to the soles; there is no wasting of the depressors of the arm; there is often slight inco-ordination of the hands; and the tendency of the disease is to lessen instead of to increase.

Prognosis.—Of a disease that consists in a morbid tendency to tissue-development, growing with the growth of the sufferer, and a little open to influence as is increase in stature, the prognosis is of necessity most grave. All that can be said is that, after the disease commences, the slower its advance is likely to be; and when growth is over and adult life is reached, its progress may almost or even altogether cease.

Treatment.—No treatment has a distinct influence on the morbid process that underlies the symptoms. In no instance has its course been arrested. Arsenic seems, in some cases, to hinder for a time the increasing weakness, but frequently it has not even an apparent influence. The same may be said of cod-liver oil. The tendency to the accumulation of fat in the muscles does not contra-indicate cod-liver oil, since the muscular fibres seem to suffer less when there is fat than when there is simple fibrous tissue. Faradisation may be employed to aid the nutrition of the muscular fibres, but its influence is small compared with that of the normal physiological stimulus to muscular nutrition—muscular exercise. Systematic movements, so arranged as to call into action the muscles that are weak, are of great importance. They should not be hurried to the point of fatigue, but should be frequently repeated. Walking should be persevered in, and a low step arranged, a few inches high, on which the patient may step first with one leg and then the other, and the height of the step may be gradually increased. Systematic rubbing of the muscles is also desirable, and passive movements may be employed to prevent or lessen the contractures, when these are threatened. It is of great importance to hinder the contraction of the calf muscles, and keep the patient as long as possible on his feet. If considerable contraction has occurred, tenotomy is necessary. The writer is known the operation to restore for

several years the lost power of walking. It is important that the tenotomy should be performed promptly when the necessity for it has arisen, before the muscles suffer further from disuse. In the later stages of the malady, the danger of pulmonary disease must be remembered, and its exciting causes as far as possible avoided.

W. R. GOWERS.

PSOAS ABSCESS.—An abscess occupying the sheath of the psoas or of the psoas and iliacus muscles, eventually and generally spreading beyond these limits.

Cause.—When the abscess is chronic, the usual cause is caries of the vertebræ from which the psoas muscle arises, or, more frequently, disease of the dorsal vertebræ; also sacro-iliac disease. Occasionally there is no cause assignable: the superficial erosion of the vertebræ found in these cases at the autopsy, and regarded as a consequence of the suppuration, the writer believes to be the cause. Acute psoas abscess in adults is rare, but has been seen following rupture of the muscular fibres from strain; one proved fatal in two weeks from pyæmia (Marshall). Acute idiopathic psoas abscess is seen occasionally in children.

Pathology and Course.—Caries of the lumbar vertebræ gives rise to suppuration beneath the origin of the psoas, and, following the line of least resistance and of gravity, the pus passes down the whole length of the muscle, destroying its fibres, and, when spreading (in ilio-psoas abscess) into the iliac fossa, converts the iliacus also into a sac of matter. When due to caries of the dorsal vertebræ, the pus enters the sheath of the psoas beneath the *ligamentum arcuatum internum* of the diaphragm. The abscess is more or less multilocular, especially in the psoas portion: it may be single or double. At first it is of the shape of the psoas, then it expands considerably, either from the iliacus becoming involved, or from the pus extending beyond the limits of the muscle-sheath.

When following an anatomical course, the matter leaves the abdomen under Poupart's ligament behind the vessels, and passes inwards to the adductor region. If the iliac portion passes out separately or distinctly, it forms a swelling external to the artery. Where the amount of matter is large, its relationship to the artery varies: sometimes it quite conceals it, and sometimes pushes it against the skin so that it beats subcutaneously. Once in Scarpa's triangle, the abscess forms its own sac,

and then varies very much in character. Generally it is globular, and presents in the adductor region; but, in addition or independently, it may turn outwards under the tensor vaginae femoris and open over the great trochanter. When large, it may appear double from an oblique depression on it caused by the sartorius; when small, it may simulate a femoral hernia as a small tumour at the ring, having an impulse on the patient coughing, or as a sausage-shaped swelling parallel to Poupart's ligament. It has been known to simulate inguinal hernia by travelling down the canal (Shaw).

Psoas abscess may protrude from the abdomen in other places: thus, posteriorly above the iliac crest, forming a lumbar abscess, or, turning downwards, become gluteal. It may pass through the sciatic foramen and descend the back of the thigh and even reach the leg, or following the curve of the sacrum it may present in the perineum. The extra-abdominal part may be of any size up to that of a sac holding pints; at times it causes great œdema of the leg from pressure. From the proximity of the sacro-iliac joint to the psoas muscle, and of the hip to the conjoined psoas and iliacus, secondary suppurative disorganisation of these joints may at times be seen—that of the hip being always a fatal complication.

Psoas abscess points usually in the upper adductor region; occasionally just above Poupart's ligament or over the trochanter. It may open in various parts of the back of the thigh: into a viscus (bowel or bladder) or into large arteries, aorta (Savory), iliac artery (Ashurst). It may never point, gradually receding and vanishing by caseation and absorption, and that when of large size. When double, one abscess only usually reaches the thigh. When it bursts of its own accord, it does so through a minute opening: a gush of seropus flows, and the opening soon gets blocked with flocculi; after a time these are displaced and more fluid escapes. Owing to the gradual evacuation and the protection against admission of air, the discharge is frequently quite unattended with constitutional disturbance. When quickly evacuated, inflammation of the sac follows, and pyrexia or septicæmia is usual.

Symptoms.—There may be none; old unsuspected psoas abscess being often found at the autopsy (Bryant). Early symptoms depend upon irritation of the lumbar nerve-roots—namely, sciatica, cruralgia, or neuralgia of the anterior crural. Aching across the hip and back and the base of

the sacrum: cramp, and at times paralysis. Inability to extend the thigh; bent position when standing; rotation inwards of the thigh. Children merely complain of a pain down the thigh, and always carry it flexed. Deep pressure in the abdomen, along the semilunar line, reveals a vertical, sausage-shaped, tender, fluctuating, elastic tumour (mistaken for loaded bowel, but which does not roll from under the fingers). It may or may not reach Poupart's ligament, and may be accompanied by a tumour of similar character in the iliac fossa.

The abscess may run its course without any subjective symptoms; the extra-abdominal tumour first attracting attention. When extra-abdominal, the usual physical signs show it to be abscess: and the impulse on coughing that it has intra-abdominal connection; combined pressure above Poupart's ligament and over the tumour in, e.g., the thigh, reveals fluctuation. Psoas abscess is most likely to be overlooked when symptoms of spinal or sacro-iliac disease are not co-existent.

Diagnosis.—For its most successful form of treatment, the abscess should be diagnosed whilst intra-abdominal. As stated above chronic psoas abscess must not be mistaken for loaded bowel. When in the groin the history, the imperfect reducibility, the absence of gurgling, and the presence of an intra-abdominal portion will differentiate it from hernia; while the presence of impulse will distinguish it from bubo. Acute psoas abscess must not be confounded with typhlitic abscess; this latter is generally more external, often emphysematous, and has a special history of its own.

Treatment.—(a) *Non-operative.*—Treat the cause, if discoverable, the abscess being left to itself; if the cause does not necessitate rest, the abscess, unless painful or producing œdema, will not do so. The chances of its absorbing cannot be calculated upon; and as most abscesses eventually discharge moving about hastens this end. A very large abscess, which spontaneously disappeared under the writer's observation, did not confine the patient to bed for even a day.

When inflamed and pointing, rest and fomentations are necessary; when it has discharged, a dressing of carbolic tow with iodoform (ten per cent.), is best. After the first day or two, the upright position aids discharge. A sinus usually results which can be dressed with boracic acid ointment. Tonics, according to circumstances, must be given.

(b) *Operative.* *Aspiration, Tapping.*—This is of use to relieve tension for a time

but is employed only when more radical measures cannot be adopted. Repeatedappings at one point will often determine the final pointing of the abscess. Complete evacuation should not be attempted at one time.

Free Incision.—This ought only to be undertaken when the fullest antiseptic precautions are adopted, both at the operation and subsequently. Whilst *intra-abdominal*, there are two places for opening a psoas abscess—one in the loin, the other just above Poupart's ligament; both wounds can be kept aseptic, but the former more certainly so; besides, it is the better one for drainage in the recumbent position.

Operation above Poupart's Ligament.—The incision is that for ligature of the external iliac artery. After division of the external oblique the knife is discarded; the rest of the tissues are turned up with the forefinger; and, when the fluctuating tumour is exposed, it is opened with dressing-forceps. A large drainage-tube is inserted, and a Listerian dressing, with the elastic taping bandage, applied. However opened, the abscess, if kept aseptic, should not be syringed out.

Operation in the Loin.—The patient being in the colotomy position, a vertical incision, four inches long, is made at the edge of the erector spinæ, its centre being, in the adult, two inches above and in the same line as the posterior superior iliac spine. Everything is divided till the quadratus lumborum is reached; this is then incised to the extent of two inches in the same direction. On reaching the anterior surface of this muscle, the sub-peritoneal fat is seen—a sure guide. The finger, now thrust into the wound in the direction of the base of the sacrum, feels a fluctuating tumour, especially if an assistant makes counter-pressure on the abscess in front. Where fluctuation is most distinct the abscess is now incised. Counter-pressure and rolling the patient backward will evacuate the contents, and the finger then explores for sequestra.

A perforated drainage-tube, at least three-eighths of an inch in calibre, and long enough to reach the iliac fossa, is then inserted, and its mouth stitched with two sutures to the skin wound, flush with the surface. The rest of the wound is now closed with deep and superficial sutures. Where full Listerian dressings (with spray) are used, the abscess need not be syringed out. Daily dressings are required for ten days; then the drainage-tube is shortened three inches, and at the end of three

weeks removed. In successful cases there may be no discharge of matter after the operation, the wound closing round the tube by primary union, and uniting completely on its removal. Two such cases have occurred to the writer. The patient must remain supine, with the thighs bent, and a pad firmly bandaged over Scarpa's triangle and along the line of the abscess in the abdominal walls.

When *extra-abdominal*, the abscess can be opened at its most prominent point; but the adductor region of the thigh should, if possible, be avoided, since it is impossible to ensure asepticism in that position. The writer has reached such an abscess through an incision outside the rectus femoris below the iliac spine, and thus ensured its evacuation away from the neighbourhood of impurities. When the abscess is opened in the inguinal region or thigh, the supine position is the worst for drainage, and the writer prefers getting such cases out of bed at the earliest opportunity.

Where psoas abscess is the result of sacro-iliac disease, and where matter is also presenting behind, over the joint, this posterior abscess should be opened and the joint explored. The psoas abscess may be finally evacuated by the same incision. The writer once trephined the joint and thus reached the abscess; the patient made a good recovery. C. HILTON GOLDING-BIRD.

PSORIASIS. (*Synon.* Lepra, Alphas.)

Definition. — Psoriasis is a non-contagious chronic disease of the skin, attended with the formation of roundish, slightly raised red patches, thickly covered with pearly-white scales.

Symptoms and Pathology.—Psoriasis, though an inflammatory disease, is one in which the inflammation is often so slight as to escape notice. At other times, it is well marked and attended with the usual signs of redness, itching, and other subjective sensations. The eruption consists at first of small slightly raised red patches, which spread at the margin and quickly become covered with silvery-white scales; these form rapidly, and as the disease increases are shed in great quantities. In some few instances the scales are not shed, but become heaped up into conical masses. In psoriasis there is no moist exudation on the surface of the skin, but it is not difficult to produce, artificially, an exudation of this kind by over-stimulating the patches, especially when they are present on the flexor surfaces of the body. Under these circumstances the disease may be easily mistaken

for eczema. The white scales are a characteristic feature of the disease; they consist of imperfectly formed, dry, epidermic structures, the silvery-white appearance being due to the presence of air in this epidermic accumulation. Psoriasis spots have a strong tendency to spread at the circumference and heal in the centre, and thus ringed or gyrated patches are produced. As the spots disappear they often leave behind considerable pigmentation of the skin.

The disease may attack exceptionally any part of the body, but is not common on the penis, scrotum, and face below the forehead, and very rare on the soles and palms. There is, however, a common form of dry eczema of the palm, which is often miscalled Psoriasis palmaris. The parts of the body most liable to the disease are the extensor surfaces of the limbs, especially the point of the elbow and the skin just below the patella; when, however, the disease is scattered in small spots over the trunk (Psoriasis guttata) the elbows and knees often escape. The disease is generally developed symmetrically on both sides of the body. It is probable that psoriasis does not attack the mucous membranes; there is, however, one form of leukoplakia buccalis which has a superficial resemblance to psoriasis, but it does not occur especially in those subject to that disease, and is probably not in any way related to it nor to ichthyosis, by which name it is sometimes erroneously called.

Etiology.—Psoriasis never occurs in infants at the breast, and hardly ever before the age of four or five; in this respect it presents a strong contrast to eczema. It is equally common in males and females. There are two varieties of psoriasis commonly met with. One appears for the first time in early life, usually before the age of twenty; it is attended with little or no itching and much scaliness; it almost invariably recurs after longer or shorter intervals; those subject to it generally have a fresh pink-and-white complexion. The other variety appears later in life, is attended with more marked inflammatory symptoms and especially with itching; the scales do not accumulate to any considerable extent. This variety is rather common in gouty families. The exciting causes of psoriasis are quite unknown.

Diagnosis.—A typical case of psoriasis cannot be mistaken for any other disease. In an irregularly developed form the disease may be confounded with dry eczema, lichen planus, tinea tonsurans of the trunk, and

scaly syphilitic eruptions. Psoriasis may be distinguished from dry eczema (1) by the fact that it generally attacks the extensor surfaces of the limbs; (2) that the patches are more raised and scaly, especially at their margins, which are always more defined than in eczema; (3) they heal first in the centre; (4) the history of the case. It is difficult to distinguish confluent patches of lichen planus from psoriasis. For the differential diagnosis, see *Lichen Planus* under PLANUS. Tinea tonsurans of the trunk sometimes assumes the appearance of healing psoriasis, but a few scales scraped from the surface, treated with liquor potassæ and examined under the microscope, will often aid the diagnosis. Psoriasis is perhaps more likely to be confounded with a squamous syphilide than with any other eruption. This is especially liable to occur when the psoriasis is in the form of crescentic patches or rings, and confined to the scalp and forehead. The absence of any syphilitic symptoms and the general appearance of the patient, together with a history of former attacks of the disease on the elbows and knees, will be valuable aids to diagnosis. The appearance of the eruption in psoriasis is of a more silvery-white colour and the pigmentation less than in squamous dermatosyphilis.

Treatment may be considered under two heads:—(1) General; (2) Local. To the former belong medicines and diet, and to the latter baths, ointments, and lotions. Of medicines used for the treatment of psoriasis, arsenic occupies the first place and should always be tried, unless some special circumstances contra-indicate its use. It may be combined either with acids or alkalies, according to circumstances, and should always be given either just before or after a meal. It must be admitted, however, that arsenic fails in a considerable number of cases, especially when the disease is associated with a gouty constitution. Under these circumstances, colchicum and small doses of iodide of potassium are sometimes very useful. The internal administration of turpentine or copaiba is occasionally beneficial, but they are remedies which are not usually so well borne as arsenic. Rules of diet, though not of the first importance in the treatment of psoriasis, should not be entirely neglected. In the psoriasis of the young, fat, and especially cod-liver oil, should form an article of daily food during the winter; in the psoriasis of middle life, especially if there be any gouty tendency, an abstinence from sugar, coffee, and beer is indicated.

(2) Of local remedies, baths are, on the whole, the most satisfactory and effective. The removal of psoriasis by baths is more lasting than by other local means, probably because the remedy is not simply local. An ordinary warm alkaline bath, in which the patient can soak for half an hour every evening before going to bed, is both an effective and pleasant remedy. The temperature of the bath may be regulated to suit the taste of the patient, and the addition of from two to three ounces of carbonate of potash will be sufficient for a full-sized bath. The best mineral waters for the treatment of psoriasis are those of La Bourboule in the Lower Auvergne; the local effect of these waters is also excellent. When psoriasis covers a very large area, it is not easy to apply local remedies except in the form of baths; but when the patches are confined to the limbs or scalp, tar lotions, especially the liquor carbonis detergens, are often very useful. The latter remedy may be used either pure or diluted with spirit, and painted on the spots with a large camel's-hair brush; thus applied it dries quickly, and is one of the best as well as one of the least disagreeable remedies. Goa powder (chrysophanic acid) has long been a favourite remedy in India for ringworm, psoriasis, and other scaly diseases. There are, however, several objections to its use. (1) Chrysophanic acid stains both the skin and clothes; (2) it is apt to set up too much inflammation, and thus cause considerable annoyance to the patient; in a few instances the writer has seen grave symptoms produced when chrysophanic acid ointment has been used over a large area. (3) The most serious objection to its use, however, is that psoriasis returns more quickly when removed by this means than when removed by any other method. Pyrogalllic acid ointment (ten to twenty grains of the acid to the ounce) is a useful local remedy, and not quite so disagreeable as chrysophanic acid ointment.

ROBERT LIVEING.

PSORIASIS BUCCALIS. — **LEUCOFLAKIA.**—This disease, which has long been known to surgeons, has in recent years attracted a large amount of attention in consequence of its relations to epithelioma. It has been more particularly described in connection with the Tongue, where its tendencies appear to be most serious, but all parts of the buccal mucous membrane are liable to the complaint.

Etiology.—Habitual irritation of the affected parts, especially in connection with

smoking, seems to be the chief causative agent; but the disease sometimes appears, without obvious exciting cause, in patients subject to psoriasis and other dry chronic forms of cutaneous eruption. Its relation to syphilis is somewhat doubtful, for although a history of hard chancre, with the usual sequences, may often be obtained in the great majority of cases, its origin is independent of ascertainable constitutional infection; and it appears probable that the rôle of syphilis is that of a common and not of a specific source of irritation, mucous tubercles, gummata, &c., acting merely by establishing an instability of the tissues in the parts attacked and a consequent susceptibility to malignant influence. In accordance with this theory of origin the disease is far more common in men, the consumers of tobacco, than in women, 101 cases out of 110 collected by Mr. A. E. Barker belonging to the former sex.

Symptoms.—The lesion as it appears upon the mucous surface of the lips, cheeks, palate, or tongue, is at first seen in the form of hyperæmic patches, which become developed into dull, whitish, roughened plaques of hypertrophied epithelium; and at a later stage may be associated with shallow fissures in the situation of the normal folds of the mucous membrane. On examination of the affected tissues, the epithelium is found to be more or less thickened and opaque, the papillæ at first enlarged, afterwards atrophied, and the submucous tissue infiltrated with white corpuscles, which extend chiefly along the course of the vessels. The anatomical changes in the parts entail no symptoms beyond the occurrence of a little salivation in the later stages, but the remarkable tendency to merge into epithelioma is a most important point for consideration. Mr. Barker has traced this sequel in no fewer than 43 instances out of 110 cases of buccal psoriasis.

The condition must be distinguished from the irregularly distributed scars and deep fissures left by the healing of gummatus lesions in tertiary syphilis.

Treatment.—All sources of local irritation, causative or otherwise, must be removed, the diet carefully regulated, and the mouth kept clean. The patients should be warned as to the possibility of remote trouble, and be kept under observation.

WILLIAM ANDERSON.

PTERYGIUM.—*Cause.*—The starting-point of a pterygium is generally an ulcer at the margin of the cornea, which, in

healing, catches a morsel of the limbus conjunctivæ and draws it towards the cicatrix, throwing the mucous membrane into a triangular fold. The ulcer then forms anew in the cornea immediately inside the cicatrix, and the point of conjunctiva is drawn into it again, and is carried a little further into the cornea, and so on.

The hollow lying between a PINGUECULA and the margin of the cornea is apt to lodge small foreign bodies, which cause shallow marginal ulcers, and these, in healing, draw the pinguecula over on the cornea.

In this country pterygium is a rare affection, but it is not uncommon in countries or localities where the air is filled with fine sand or other minute particles.

Symptoms.—Pterygium consists in a vascularised thickening of the conjunctiva, triangular in shape, situated most usually to the inside of the cornea, sometimes to its outer side, and rarely either above or below it. There is frequently, but not always, a tendency of the growth to advance into the cornea, as above mentioned; but it seldom reaches the centre, and still more rarely extends quite across the cornea. Vision is not affected, unless the growth advance over the centre of the cornea. There is no pain, and the disfigurement alone is what the patient complains of.

Treatment.—Unless the pterygium be very thick and have invaded the cornea to some extent, or be progressing over the cornea, it is well to let it alone; the more so as, by removing it, a perfectly normal appearance is not given to the eye, for a mark is necessarily left, both on the cornea and on the conjunctiva.

If the growth be progressive, or very disfiguring, it should be removed, other proposed methods of dealing with it being futile. This may be effected either by ligature or excision.

In the method by ligature, a strong silk suture is passed through two needles. The pterygium being raised with a forceps close to the cornea, one needle is passed under it here, and the other needle in the same way close to its base, and the ligature is drawn about half-way through. The thread is cut close behind each needle, thus forming three ligatures, which are respectively tied tight. In four or five days the pterygium comes away.

In excision, the apex is seized with a forceps and dissected up, either with a scissors or small scalpel, care being taken not to injure the true cornea. The dissection is continued towards the base of the ptery-

gium, where it is completed by two convergent incisions meeting at the base. The mucous membrane in the neighbourhood of the base is separated up somewhat from the sclerotic, and the margins of the conjunctival wound brought together with sutures.

H. R. SWANZY.

PTOSIS—Drooping of the Upper Eyelid. See *Third-Nerve Paralysis* under **OCULAR MUSCLES**, Affections of the.

PUDENDAL HERNIA.—This rupture appears in the posterior inferior part of the labium. The neck of the sac lies between the ramus of the ischium and the vagina. The sac on making its way to the labium must pass through the anterior fibres of the levator ani. This form of rupture is most common in women past middle life, who have borne several children. The protrusion is usually small and contains small intestine. It has been mistaken for a labial cyst. It is usually readily reduced, and gives but little trouble. It has been strangulated, and has—when in that condition—been successfully reduced by taxis. It would appear that in no reported case has herniotomy been required. FREDERICK TREVES.

PULMONARY ARTERY, Wound of the.—This is a rare accident, but it occasionally takes place in stabs or shot-wounds. In the former it may be the only vessel wounded, from its anterior and comparatively superficial position in the chest. If the vessel be wounded before its bifurcation, the accident must necessarily be of an exceedingly fatal character. On account of the way in which the serous pericardium wraps round both this vessel and the aorta, the wound must perforate the upper part of the pericardium, and extravasation of blood from the vessel must take place directly into the pericardial sac, and thus cause very speedy death, as in incised wounds of the heart, by filling up this sac with blood and impeding the action of this viscus. Such a wound may perforate through into the ascending part of the arch of the aorta, and thus form a communication between these two vessels.

In those cases in which the artery is wounded beyond its bifurcation, the blood extravasates into the root of the lung, and hence into the posterior mediastinum. Such wounds, which are generally of a very complicated character, are sometimes the cause of immense extravasations of blood into the posterior part of the chest. The prognosis in all such cases is exceedingly grave.

The diagnosis is generally obscure, the symptoms much resembling those of HÆMOTHORAX, the treatment also being the same.
H. G. HOWSE.

PULPY DEGENERATION OF SYNOVIAL MEMBRANE. See JOINTS, Diseases of.

PULSE.—The pulse affords valuable indications for the surgeon, and a careful study of it is essential for diagnosis, prognosis, and treatment. It is one of those indications of the condition of a patient which is very readily obtained, and obtained also without the intervention of instruments; and for this reason it is deserving of very special attention. The *tactus eruditus* applied to the radial artery at the wrist may give the first warning to the operator that the patient has cardiac trouble, and is therefore a bad subject for anæsthetics or the knife; or that he has a granular contracted kidney, and is, therefore, not well fitted for operative interference. It tells him more, probably, than any other source of information, concerning his patient's 'strength' (i.e. the strength of the muscles of organic life), and of his progress towards recovery or death; and, above all, the administration or withholding of stimulants can only be properly regulated by one who is able to value properly the indications afforded by the pulse.

The pulse is usually 'taken' by placing the tips of the right index, middle, and ring fingers upon the radial artery of the patient, as it lies upon the bone just above the left wrist. With each stroke of the heart the artery is felt to dilate. This constitutes the 'pulse,' of which we have to note the rapidity and the other characters which form the subject of this article. The radial artery is usually selected because of its accessibility and convenience. Occasionally, the radial artery (owing to abnormal distribution or other cause) is not available, and then we may have recourse to the temporal, brachial, or any other superficial artery of the body.

By feeling the pulse we estimate mainly two things—(a) the rate at which the heart is working; (b) the pressure of blood in the artery. The rate is always stated in terms of pulsations per minute. The pressure is estimated by noting the force needed to stop the pulse with the fingers. In the healthy person it may be stated, as a rule, that pressure is inversely as the speed. A heart that hurries is often to some extent inefficient, and fails to maintain the pressure in the vessels. Again, the pressure in the

vessels is far more dependent on the state of the arterioles and capillaries than on the force of the heart's action, and raising the pressure has the effect of raising the tone of the vagus centre in the medulla, and consequently of slowing the heart. The converse also holds good.

THE PULSE-RATE varies with *age*, as shown by the following table:—

In the fœtus	140 to 150
Newly born infant . . .	130 „ 140
During 1st year	115 „ 130
„ 2nd „	100 „ 115
„ 3rd „	95 „ 105
From 7 to 14	80 „ 90
„ 14 „ 21	75 „ 85
„ 21 „ 60	70 „ 75
Old age	75 „ 80

The influence of *sex* is considerable, and Dr. Guy has determined that the pulse of the adult female is quicker, by from 10 to 14 beats, than the pulse of the adult male.

The effect of *muscular exercise* is to quicken the pulse, the increase in pulse-rate being proportioned to the effort made. Thus, the pulse is quicker when standing than when sitting, and quicker when sitting than when the body is at complete rest in the recumbent position.

The effect of *position* apart from muscular effort is shown to be considerable. It is stated by Graves that the erect posture, as compared with the horizontal, increases the pulse-rate in a healthy person from 6 to 15 beats. This difference increases with the frequency of the pulse at the time of the experiment; thus, if it has been raised to 90 or 100 by moderate exercise, it is not unusual to find the difference 20 or 30. Dr. Graves found that this variation of pulse-rate with posture did not depend entirely upon the muscular effort involved in maintaining the posture, and that, when the position was changed by means of an apparatus which excluded the factor of muscular effort, the variations of pulse were nearly as great as when posture was changed by means of the patient's own exertions.

The pulse, according to Graves, is also 'evidently stronger in the horizontal than in the erect posture; consequently its *maximum of strength and minimum of frequency* are attained together.' This constitutes one of the reasons for placing persons horizontal for the relief of syncope.

A somewhat extended study of the effect of posture on the pulse-rate enabled Graves to conclude—

1. That the greatest difference occurs in patients labouring under fever, or in a

debilitated state in consequence of fever or any other cause. It may amount to 30, 40, or even 50, between the horizontal and erect postures.

2. That this difference decreases after the first quarter of an hour (i.e. after the subsidence of the variation due to exertion of muscular effort), but always remains considerable as long as the same position is observed.

3. That in persons not much debilitated the difference is much less, and often does not amount to more than 10.

4. Generally, the pulse-rate in the sitting posture may be taken as the mean.

5. In persons convalescent from fever or acute diseases, it is extremely useful to the physician to ascertain the comparative frequency of the pulse in the horizontal and in the erect posture. The greater the difference, the greater is the debility of the patient, and, consequently, the more guarded must his medical attendant be in allowing him to sit up for any length of time, particularly if the pulse, on his lying down, does not resume its usual degree of frequency.

Dr. Graves also asserted that, in cases of considerable hypertrophy and dilatation of the heart, the variation of pulse-rate with variation of position is often not observable, and he concludes 'that in a debilitated person, when a sudden change of position makes no difference in the frequency of the pulse, we may conclude that the heart, or at least its left ventricle, is increased in size and strength.'

The pulse-rate is influenced by *temperature*; and it has been shown that when animals are exposed to high temperatures it rises, and when exposed to low temperatures it falls. In fever there is, speaking generally, a correspondence in direct ratio between the body-temperature and the pulse-rate—i.e. they both rise and fall together, or, to be more accurate, the variations in pulse-rate usually follow by a little the variations in temperature. When the temperature is high, it is found that influences which disturb the pulse-rate (such as mental emotion, muscular effort, and posture) act with undue force, and thus it often happens that the pulse-rate runs ahead of the temperature.

The pulse-rate in fever, like the temperature, is subject to daily fluctuations, having a morning minimum and an evening maximum. In mild cases of fever a pulse of 100 is common. In more severe cases it runs up to 120 or 130; but if a rate above this (say 140) is maintained for any time it

makes the prognosis grave. Towards the end of fevers which terminate fatally, we may have a falling temperature and a rising pulse—a condition which is always grave. In heart-disease, we may have a rapid pulse with a sub-normal temperature. In tubercular meningitis or in other fevers complicated by mischief at the base of the brain, we may have a high temperature with a sub-normal pulse. In short, there is a rough correspondence between pulse-rate and temperature, and, when we find such correspondence wanting, we should always search for the cause.

We may have a very rapid pulse without rise of temperature. This is notably the case in Graves's disease or exophthalmic goitre, in which the pulse-rate may reach 160 in a minute. In poisoning by atropine, a rapid pulse occurs, due, as is supposed, to a paralysis of the inhibitory apparatus in the heart. Similarly, Guttman records a case of very rapid pulse (160), unaccompanied by rise of temperature, and due to compression of the vagus nerve by swollen lymphatic glands.

Mental and emotional excitement has been known to quicken the pulse. *Diminution of atmospheric pressure* does the same thing, and Mr. Glaisher records that in rising in a balloon from the ground to a height of 20,000 feet, the pulse-rate rose gradually from 76 to 110. It would be impossible entirely to eliminate the effect of mental excitement in this experiment.

In valvular disease of the heart the pulse is usually quickened, and especially, also, during an acute inflammatory condition such as peri-, endo-, or myo-carditis. A fatty heart often causes a slow pulse; sometimes remarkably slow, falling below 30.

The pulse may be *irregular in force and rhythm*. This may depend upon organic disease (valvular) of the heart; upon disturbed innervation, which may be central (as in tubercular meningitis), reflex (as in dyspeptic conditions), or toxic (as from digitalis and the excessive use of tobacco). Irregularity is common in old people, and seems generally (in the absence of cardiac disease) to cause no trouble, and probably does not influence the expectation of life.

Sometimes, the irregularities are very regular in their intervals of occurrence, sufficiently so to have a pseudo-mystic title, and accordingly we find in books the words *bigeminus*, *trigeminus*, and *alternans* applied to irregular pulses. The last form occurs when the left ventricle is so weakened that only every other contraction makes

itself felt at the wrist. 'Intermission of the pulse at irregular intervals may be due to similar causes. It may accompany heart-disease or may occur in persons otherwise healthy.

In considering the pulse, it must be borne in mind that the capacity of the blood-vessels is far more than is sufficient for the blood which they hold. When the vessels are relaxed, the blood does not nearly half fill them. In a 'full-blooded' man who has died suddenly, we find *post mortem* the arteries empty, and the veins by no means distended. During life, the vessels contract on their contents, but, their potential capacity being so great, it is evident that unequal contraction in different areas of the body leads to unequal distribution of blood. In health, the blood-distribution is always proportioned to the need of the part, the need to the work being done. When there is a 'determination' of blood to any part, there must be a compensating emptiness of some other part. When the surgeon stands his patient against a wall, and, passing a catheter, draws off perhaps a gallon of urine from an over-distended bladder, the sudden removal of pressure from the belly causes a sudden flow of blood into the vessels of that part, with the result that the brain and medulla are suddenly starved of blood, and the patient falls down senseless and faint.

THE VOLUME OF THE PULSE varies in individuals. It may be of different volume at the two wrists, and this may depend upon irregularity in the distribution of the radial artery, or it may depend upon some pressure or obstruction in the main trunks either inside or outside the thorax.

The pulse may be of small volume (a) from loss of blood; (b) from failure of the heart to supply the required amount to the arteries, as in mitral or aortic obstruction and cardiac failure; (c) from pressure upon the aorta; (d) from diversion of the blood-stream, producing relative emptiness of the radial artery. This occurs in peritonitis and collapse, in which there is dilatation of the abdominal vessels. It is at the commencement of peritonitis, when there is determination of blood to the abdominal vessels, and before the muscular tone of the arteries or the muscular power of the heart has begun to fail, that we get the so-called 'thready pulse' (small and hard), which is almost diagnostic of abdominal inflammation.

When the heart is hypertrophied from aortic disease, the volume of the pulse is large. In advanced atheroma of the arte-

ries, there is often a seeming increase of volume from the increased thickness and tortuosity of the vessel.

The *hardness* or *softness* of the pulse, the ease with which the pulse can be arrested by pressure of the finger, is most important from a diagnostic point of view. If the volume of blood be normal, if the left ventricle be hypertrophied and the aortic valves efficient, if the arterial wall be thickened from muscular or fibroid increase, and if the emptying of the arteries be hindered by contraction or thickening of the arterioles and capillaries, then the compression of the pulse is necessarily difficult, and we get the high-tension pulse which is so common with gouty kidneys, arterio-capillary fibrosis, and hypertrophied heart.

The causes above mentioned which, when they concur, produce a high-tension pulse in its most marked form, may not all be present simultaneously, or some of the causes of high tension may be counteracted by others which tend to produce low tension, such as deficiency of blood, mitral obstruction, cardiac weakness, or loss of tone in the blood-vessels from anæmia or acute febrile diseases. A soft compressible pulse, occurring in febrile diseases, indicates weakness and a failure of the muscles of the heart and vessels.

When the left ventricle is greatly hypertrophied and the aortic valves are inefficient, we have a very marked and forcible distension of the artery with sudden collapse, owing to the failure of the valves to maintain the pressure in the vessel. This is the *quick-bounding* pulse of some writers, otherwise known as the *water-hammer* pulse or Corrigan's pulse. Owing to the great distension of the vessels, the pulse is often *visible* in the arteries throughout the body, and visibility of pulse is to be reckoned amongst the surest indications of aortic incompetency. Visibility and hardness of the pulse also occur in advanced atheromatous disease of the vessels in persons advanced in life. It may occur also in healthy individuals in a state of nervous excitement.

A very important form of pulse is the so-called *dicrotous* pulse, in which for each contraction of the ventricle there are two pulsations in the artery.

It must be remembered that dicrotism is a physiological phenomenon which, by the use of the sphygmograph, can be seen to be always present in the pulse. It is only, however, when dicrotism reaches a high degree, that it can be detected by merely

placing the finger on the artery. Dicrotism is a sign of weakness, and appears to be due to a want of tone or failure in power of the muscular coat of the artery.

When the ventricle contracts, the tidal wave of blood distends the elastic artery; this distension ceases with the cessation of the ventricular contraction. The artery then recoils, and the force of the contracting artery closes the aortic valves and, at the same time, gives an impulse to the blood in the vessel, which travels to the periphery. This 'dicrotic' wave, though always present, only becomes manifest when it is excessive. The elasticity of the arteries depends upon (a) yellow elastic tissue, the action of which is mainly, if not entirely, mechanical and independent of central control, and (b) muscular element, in which the elasticity is 'vital,' and subject to great variations. The amount of elastic and muscular elements present in an artery bear an inverse proportion to each other, the latter increasing as the former decrease. The muscular elements in the radial artery at the wrist are present in relatively large proportions, and one of the effects of their activity is to check the oscillations of the vessel and render the dicrotic wave impalpable. When the artery loses its tone and the muscular coat is paralysed, as happens in acute and severe febrile conditions, then the dicrotic wave is easily felt, and its presence is made the more striking in consequence of the smallness of the tidal wave, caused by the failing power of the ventricle.

A dicrotic pulse is usually the accompaniment of high fever, and indicates that the powers of the patient are failing. It is sometimes the precursor of hæmorrhage (according to Graves), and is often observed as an immediate sequel of extensive hæmorrhage. In fever, says Graves, a dicrotous pulse, which is at the same time hard, is a *very bad* symptom if it lasts more than twenty-four hours; when succeeded by epistaxis, and when it disappears after moderate epistaxis, it is not bad; when it lasts for many days without any tendency to hæmorrhage, the case, nine times out of ten, ends fatally.

'In hæmoptysis, epistaxis, and internal inflammation, a very hard dicrotous pulse sometimes occurs, which resists all treatment and portends a fatal issue; no matter how much the other symptoms may improve, so long as the pulse continues of this character, the patient is in imminent danger.'

THE PULSE-RESPIRATION RATIO is a point which always demands attention. As a

rule there are, on an average, four beats of the pulse to each respiratory act, and the healthy individual has eighteen respirations and seventy-two pulse-beats per minute. Any persistent disturbance of this ratio should excite suspicion. If the pulse-respiration ratio changes from 4:1 to 3:1 or 2:1, the lungs should be carefully examined, and in the majority of cases they will be found the seat of disease. The quickening of the respiration is usually proportioned to the amount of lung-damage. Thus, in double pneumonia, where the amount of lung available for respiration is reduced to a minimum, the breathing is often enormously quickened, and, notwithstanding great rapidity of the pulse, the pulse-respiration ratio may be 2:1.

In pleurisy and bronchitis the ratio is usually less disturbed than in pneumonia. Sometimes, while the pulse is quickened the respirations are slowed. This is observed in a very marked degree in opium-poisoning, in which the respirations get gradually slower, while the rapidity of the pulse is above normal. In some cases of delirium tremens the same phenomenon is observed. In hydrophobia also, towards the end of the case, the respirations may become very slow and very unequal in rhythm, while the pulse remains rapid.

Speaking of the importance of the pulse-respiration ratio, Graves says: 'A quickening of the breathing in fever, without any particular lesion of the thoracic viscera, is always a proof that the muscular powers of organic life have been injured; that the diaphragm and respiratory muscles are impeded in their functions, and that the case is of a dangerous character.'

The pulse affords valuable *indications for treatment*, especially in acute conditions, whether medical or surgical, in which the administration of stimulants is necessary to enable a patient to tide over a crisis. To use stimulants with intelligence is of the greatest importance, and the surgeon must always bear in mind the difference between stimulants and food, a difference of the same kind as that which exists between the spur and a feed of corn in relation to a horse. The analogy is only partly correct, however, for there can be no doubt that alcohol may serve as a food, and especially would this seem to be the case in fevers with high temperature.

If the pulse tells us that the muscles of the heart or arteries are failing, if want of force is being compensated by undue rapidity, if the pulse be soft, compressible, or especially if it be dicrotous, then stimulants

re advisable, and, judiciously given, will enable a patient to recover from a condition which might otherwise be fatal.

Alcoholic stimulants act quickly, and the surgeon should always ascertain, within a quarter of an hour or so after their administration, if the indications for which the stimulants are given have diminished. If stimulants are being useful to a patient, this should always be the case. The rapid pulse should be slower, the soft pulse firmer, and the dicrotous pulse less dicrotous. Or, if stimulants be administered to quicken the action of a slowly acting heart, the end ought to be fulfilled and the pulse ought to be more rapid within a short time of administering the stimulants.

It is a golden rule never to give a dram of alcohol which is not necessary, it to keep it in reserve in case of need. Stimulants, in acute conditions, should be given in small doses and at frequent intervals. Directly the indications for which the alcohol has been administered have been met, it should be discontinued, or the dose lessened. It is especially in acute cases of high fever, in which it is impossible to give food, that alcohol is of use. In cases of failing heart from hæmorrhage, alcohol is generally contra-indicated, and solid food, which is easily digested, is likely to be of more service to the patient.

G. VIVIAN POORE.

PURPURA.—*Definition.*—Purpura is, in the modern acceptation of the term, synonymous with non-traumatic hæmorrhage into the skin and mucous membranes, and occurs in both sexes and at all ages.

Etiology.—The causes of cutaneous hæmorrhages are very numerous, and may be classified under five heads:—

1. Blood-alterations caused by—(a) specific fevers, especially typhus, variola, hæmorrhagica and epidemic cerebro-spinal meningitis; less often by typhoid, measles, scarlatina, acute septicæmia, pyæmia, and phthisis; (b) snake-poison; (c) some drugs, where there is an individual idiosyncrasy, as iodine, iodide and bromide of potassium, quinine, salicylic acid, copaiba, and ergot of rye, chloral, &c.; (d) certain general diseases, as scurvy, hæmophilia, leucocythæmia, pernicious and other anæmias, rickets (scurvy rickets); (e) cancer, as in tuberculosis and cancer.

2. Many diseases of the viscera, including some of those of the spleen, liver (especially cirrhosis and chronic jaundice), intestines, kidney (especially chronic

Bright's disease), lung and cardio-vascular system, acting probably and mainly through the sympathetic.

3. Want of support to the vessels, due to—(a) Relaxation of the tissues, as in old age (*P. senilis*), getting up after long illnesses, parturition, &c.; or (b) the existence of other eruptions, especially bullæ or wheals.

4. Sudden changes in the circulation, as in purpura in the new-born (*P. neonatorum*).

5. Diseases of the nervous system—(a) Functional, in connection with shock, grief, epilepsy, angina pectoris, and other neuralgias; (b) organic, as in tubercular meningitis, plugging of cerebral sinuses and some other serious lesions, also in posterior myelitis, injuries to nerves, &c.

Pathology.—Blood may escape from the vessels by rupture, diapedesis, or by transudation of blood colouring matter only; the last two play an unimportant part, and there is no doubt that, in the majority of cases, rupture of the vessel takes place. This may occur from—increase of blood-pressure behind the point of rupture, especially if suddenly produced, and the commonest cause of this is some obstruction in the vessel, which may be due to stasis from inflammation or some external pressure, thrombosis or embolism. Extreme contraction of the vessels on the one hand, or dilatation on the other, may also lead to rupture of the vessel. In another class of cases the rupture may be due to changes in the vascular walls, from inflammation or degeneration. A third class are due to changes in the nervous system, which may produce variations in the calibre of the vessels or alterations in the nutrition of their walls.

Blood may be extravasated into the tissues either between the layers of the epidermis or into the papillæ and corium; or more rarely into the sweat-glands, hair-follicles, and subcutaneous tissues. The changes that take place in the absorption of blood-clots are as follows:—The serum is first absorbed with the broken-down corpuscles, later the fibrin shrinks, liquefies, and is also absorbed. The variety of colours seen during life is mainly due to hæmatin changes. The hæmatin escapes from the corpuscles and stains the fibrin and serum; after they are absorbed it remains as yellow or reddish-brown granules, either scattered or aggregated. In some cases the hæmatin remains in the corpuscles, and then these shrink into a granular mass, and the hæmatoidin finally separates into yellowish or

ruby red rhombic columns or tables. Small hæmorrhages leave no trace behind, but the larger or deeper ones leave a more or less permanent pigmentation due to hæmatoidin.

When hæmorrhages take place into mucous membranes, erosion of the membrane frequently results, and hence it is common to find ulcers of this kind, often of a considerable size, in the stomach, intestines, &c.

Symptoms.—The most common are petechiæ or spots beneath the epidermis, from an eighth to half an inch in size, of a bright red to a claret or deep purple colour at first, but changing, as absorption takes place, into the bluish, greenish, yellowish, and brownish tints of a fading bruise; round or irregular in shape, sharply defined, but with finely ragged edges. They are seldom raised, are unaltered by pressure, come anywhere, but mostly in dependent positions, are never transitory, never increase in size except by fresh hæmorrhages, and remain visible after death; they are unattended by itching or any other alteration of sensation.

Besides the numerous cases in which the cause is known, there is a large remanet occurring in apparently healthy individuals, presenting some varieties which necessitate a separate description; but it must always be borne in mind that the differences between them are mainly in degree, or in the accompanying symptoms.

Varieties.—These are three in number.

1. *Purpura simplex.* This may be considered as the type of the affections to which the name of purpura was formerly restricted. In this form, apparently spontaneous hæmorrhages make their appearance suddenly, often in the night, and generally without previous symptoms. In adults the hæmorrhages come first, most frequently upon the lower extremities, especially the flexor aspect of the thighs and calves, and in children upon the neck and upper part of the arms, but almost any part may be attacked. The lesions are mostly petechial, of any size, roundish or oval, but may be irregular. They come in crops, are usually symmetrical but occasionally unilateral, and give rise to no inconvenience. Fresh crops of petechiæ continue to appear for a period varying from a few days to a few weeks.

Sometimes the outbreak of hæmorrhages is preceded by lassitude, aching in the limbs, especially the calves, anorexia, and general malaise, but these symptoms are more common, though not invariably present in 2. *Purpura hæmorrhagica*, which may

be regarded as an exaggerated *P. simplex*, and is often preceded, in addition to the above symptoms, by headache, great debility, and even convulsions. The lesions present every variety of aspect; beginning upon the legs and lower part of the trunk, they rapidly involve by successive crops the whole of the body-surface. Sooner or later the hæmorrhages take place internally, especially from the mucous membranes, into the parenchyma of organs and various serous cavities; and epistaxis, hæmoptysis, hæmetemesis, hæmaturia may ensue so profusely as to rapidly undermine the strength of the patient and lead to speedy death by exhaustion; or the fatal event may be produced by the position of the hæmorrhage—e.g. the meninges or brain-substance. Or, again, the bleeding may be more moderate and continue for a few weeks, or may cease altogether in about a fortnight, either abruptly or gradually, the general health being affected in proportion to the amount of the hæmorrhages.

3. *Peliosis*, or *purpura rheumatica*, generally described as a variety of purpura there can be, however, little doubt that it is an exudative erythema, with superadded cutaneous hæmorrhages, which in rare instances have amounted to *P. hæmorrhagica*. The affection is uncommon; in the patient complains of malaise, lassitude and pains of moderate intensity in the limbs, especially the joints, which are often slightly swollen and tender; after lasting a few hours up to a day or two, during the evening or night an eruption appears, and the pains then often abate, but sometimes the eruption precedes the pain. The eruption is generally most abundant in the neighbourhood of the joints in which the pain has been greatest, and upon the calves; the knees and ankles are always, the elbow and wrists frequently, and the trunk rarely involved. The eruption is petechial upon the calves and may be so round the joints but more frequently the lesions there consist of slightly raised papules or patches, bright red at first, like an erythema papulatum but unaltered by pressure and soon becoming purplish. The temperature may be raised three or four degrees, but this elevation has no apparent relation to a fresh attack, the joint-affection, or the eruption, and the temperature is often normal when all the other phenomena are as severe as in those in which there is marked fever; the pains subside in a few days, but the hæmorrhages take the usual time for absorption. Even without the recognisable presence of rheumatic fever, valvular heart-disease has

occasionally ensued. Albuminuria and hæmaturia have been seen, but in rare instances.

Diagnosis.—Purpura simplex has to be distinguished sometimes from erythema papulatum and flea-bites. The fact that the purpura spot is unaltered by pressure distinguishes it at once from erythema, which only resembles when the petechiæ are of a brighter colour than usual. The later stage of flea-bites is exactly like the petechiæ of disease, but they do not come suddenly in crops, have a ring of congestion round them at the commencement, and a central unctum is discernible for the first few days. P. hæmorrhagica has only to be distinguished from certain other symptomatic hæmorrhages. Scurvy most closely resembles it, but this disease is invariably due to the deficiency of vegetables in the dietary, while P. hæmorrhagica has no relation to diet; moreover, the distinctive premonitory symptoms—great prostration, frequent faintings, and later, swelling of the gums, loose teeth, and the characteristic brawny swelling of the limbs—always accompany a well-marked case of scurvy.

The history of hæmophilia, and the general symptoms of leukæmia and pernicious anæmia, will always distinguish these diseases from P. hæmorrhagica.

The diagnosis of P. rheumatica is easy; joint-pains, and purpura without symptoms of other disease, are generally sufficient to establish it. The rare cases of embolic purpura, due to ulcerative endocarditis in the course of rheumatic fever, would be distinguished by the high temperature and more general condition.

Prognosis.—The majority of cases terminate favourably, but the duration is very variable; and as we have nothing to guide us as to the course the case will pursue, even the simplest cases sometimes passing without assignable cause into severe forms, it is well to be guarded in prophesying the termination. In purpura rheumatica the patients nearly all get well, but often take a long time, and the disease is very liable to recur.

Treatment.—Cases of moderate severity often require no treatment, or only that appropriate to the general condition, in which the purpura is intercurrent; but rest in the horizontal position is one of the most important precautions, and should be rigorously insisted upon in all cases except the slightest. In purpura hæmorrhagica, every effort should be made to support the strength from the first by nourishment in an easily assimilable form; but diet has no influence

upon the hæmorrhage, except when it is dependent upon general disease like scurvy. When the hæmorrhage is sufficiently severe to be treated, or is the only symptom present, the drugs upon which most reliance can be placed are the liquid extract of ergot and ergotin injected subcutaneously. Turpentine internally and by inhalation, ice internally and externally, are often useful, and local astringents may sometimes be tried in severe cases: in one apparently desperate case, faradisation of the whole surface seemed effectual. Perchloride of iron, quinine, and general astringents have their advocates, but, from what is already known of the pathology of purpura, it is not surprising that in some cases all remedies should fail.

Purpura that is intercurrent in general conditions rarely requires separate treatment, except in diseases like scurvy and hæmophilia, where it is very profuse. The treatment of peliosis rheumatica is scarcely more satisfactory; rest is essential, and a liberal dietary should be prescribed. Salicylate of soda often gives relief to the pains, though it does not seem to exercise much influence over the general course of the disease; quinine and iron separately or in combination are beneficial in some cases, but many run their course uninfluenced by treatment. People who have had one attack should take the same precautions as those who have had rheumatic fever, and carefully guard against exposure to rapid alterations of temperature.

PUSTULE, MALIGNANT. *See* MALIGNANT PUSTULE.

PYÆMIA is the name given to a group of morbid processes, which are characterised generally either by peculiar local and constitutional symptoms, or by the presence in the blood of a specific infective organism. Two fairly well-marked forms may thus be distinguished; one, in which the prominent symptom is fever, caused by the entrance into the blood of an organism having the power of multiplying itself indefinitely, accompanied or not by local lesions such as venous thrombosis, embolic abscesses in the viscera, acute suppurations of the serous or synovial spaces, multiple abscesses in the

connective tissues, and eruptions on the skin; the other, in which local troubles of the same nature are present, but in which the constitutional symptoms do not attain such prominence, and the infection by a specific pathogenic organism is uncertain.

In spite of the views held by Koch, Davaine, and others, as to the relationship between pyæmia and septicæmia, it does not seem advisable to regard the presence of metastatic abscesses as the criterion by which to distinguish one from the other. They are not of necessity present in all cases of pyæmia; the infective process may prove fatal before there is time for them to develop; and some, at least, may be present under other conditions without there ever having been true infection at all.

Burdon Sanderson, in his lectures on the 'Infective Processes of Disease' (*Brit. Med. Journ.*, Dec. 29, 1877), says: 'What I mean by septicæmia is a constitutional disorder of limited duration, produced by the entrance into the blood-stream of a certain quantity of septic material. It must, therefore, be regarded, not so much as a disease, but as a complication, differing from pyæmia, not only in the fact that it has no necessary connection with any local process either primary or secondary, but also in the important particular that it has no development. Pyæmia is a malignant process which goes on and on to its fatal end; but in the case of septicæmia, inasmuch as the poison which produces it has no tendency to multiply in the organism, there is no reason why the morbid process should not come to an end of itself, unless either the original dose is fatal or a second infection takes place from the same or another source.' The one is septic intoxication due to the absorption of chemical products of decomposition, exceptionally attended by local mischief; the other embraces a group of diseases, of which one at least is due to the multiplication in the system of a pathogenic organism, and in all of which metastatic inflammations so frequently occur that their presence is held to stamp the disorder as pyæmic, even when no evidence of a germ can be found. From the evidence collected by the committee of the Pathological Society it seems probable that among the cases returned as pyæmic were some (1) in which the constitutional symptoms were so severe as to prove fatal before any local manifestations could have made their appearance; others (2) in which these were present as complications often causing death from their affecting vital organs; and (3) a third class, in which local

thrombosis gave rise to local abscesses (often confined to the lungs) and death, with the evidence of any pre-existing systemic infection.

There may be distinguished in the majority of cases of pyæmia two series of morbid processes: first, the general constitutional disturbance due to the system poisoning; and, secondly, local metastatic inflammations consequent on this, but sometimes present independently. The former, these, it is admitted, is caused by the circulation of some animal poison in the blood, but beyond this fact nothing is certainly known. Pyæmia derived its name 'puilent infection,' from the idea that the material introduced was pus, which was carried round by the blood and deposited in various parts affected. It was pointed out in proof of this, that the disorder was commonest after injuries involving structures full of venous channels, particularly if the veins when cut were in any way prevented from collapsing; that it very rarely occurred in wounds which healed by the first intention; and that it was especially frequent when the pus spread from the seat of injury along the planes of cellular tissue surrounding and bathing the exterior veins whose swollen and thickened walls enclosed a broken-down semi-fluid clot. It was this pus-like fluid, supposed to be a secretion of the inflamed *intima*, and generally prevented from entering the circulation by the protecting coagulum, which sometimes was carried off to form metastatic deposits.

Further observation, however, soon made it clear that the metastases were not merely deposits of pus in the viscera, but true inflammatory foci, abscesses set up by the irritant conveyed to them by the blood, and, further, that this irritant could not be healthy pus, for, when this was injected into the blood-stream, it only set up a slight and transient pyrexia, and if it blocked blood-vessels anywhere, caused, not an abscess, but a purely passive mechanical infarction. If, however, the pus had been allowed to remain exposed to the air and become putrid, the most violent reaction followed, all the symptoms, local and constitutional, of pyæmia setting in with extreme severity. Evidently some cases had been produced during the process of decomposition (by which was understood ordinary putrefaction, attended by the presence of minute organisms), and it was once concluded that pyæmia was due to the entrance into the circulation of the septic germs. The unorganised poison

could be extracted from putrefying pus caused septic intoxication, in which the severity of the symptoms, other things being equal, was directly proportionate to the quantity injected, and there was no reproduction of the poison in the animal's body, so that a drop of its blood taken immediately after death contained only a minute proportion of the original amount, and caused scarcely any disturbance. If, on the other hand, the organisms found their way in, so, though the general symptoms might be the same, they did not set in at once, and the poison while in the blood increased in quantity, and perhaps in virulence, to such an extent that the most minute trace was sufficient to cause the most unlimited effect. It was a living poison, associated with the presence of living organisms, and from the analogy of such diseases as that caused by the bacillus of anthrax, they must be the cause of the symptoms; like living organic ferments, which, while growing, can evolve at the expense of the material they absorb some substance capable of producing rapid and extensive chemical changes. This was septic infection.

Putrefaction ($\sigma\eta\psi\iota\varsigma$), in the ordinary acceptance of the term decomposition with the evolution of stinking and offensive gases, is not, however, absolutely essential. Though they must be very closely allied, and usually do occur together, the organism that is the cause of pyæmia cannot be the ordinary bacterium termo, or the equally common form of bacillus. In certain cases putrefaction is not present at all; the exceedingly virulent poison in the bodies of those who have died of puerperal peritonitis diminishes in activity as decomposition advances; and Dowdeswell (*Proc. Roy. Soc.*) has shown, by experimenting on animals after the fashion of Davaine, that the action of putrid bullock's blood, so far as its specific infectivity is concerned, is always uncertain. In summer, kept from five to ten days, it was usually most active; after a longer time its power diminished; and in winter (and this was not due to the temperature at which it was kept) it never became infective at all, the experiments being uniformly. Whenever it was active, and then only, an organism was present, peculiar in its microscopic appearance and its dimensions, so that this form at least of so-called septicæmia must be regarded as the result of infection by a specific germ. This germ may or may not be the cause of pyæmia in man; very likely there are many possessing this property, different species or different forms of the same, and

it may be that at some future time we shall be able to isolate them, and distinguish them from each other as easily as we now can the bacillus of anthrax. All that may be inferred at present is, that in decomposing animal matter there are sometimes present organisms, closely allied to the common forms but not identical with them, capable of acting as the most powerful infective poisons.

It is easy to conjecture from this how surely pyæmia follows on the neglect of any of the ordinary hygienic principles: impure air, defective drainage, unhealthy occupations, overcrowding (particularly if there are at the same time many open suppurating wounds), careless dressings, the use of ward sponges. Everything, in fact, that tends to the accumulation or decomposition of organic matter directly conduces to it. For the same reason it attacks some persons more readily than others, those especially being liable in whom, either from privation or disease of important excretory organs, it may be imagined that the blood is loaded with effete nitrogenous material; and in this way may be explained the well-known predisposing action of the puerperal state, intemperance, fatigue, loss of sleep, mental anxiety, and acute fevers. Children, in spite of the large relative amount of waste material, owing to the activity of their excretory organs, absence of mental disturbance, and ready power of repair, are more exempt than adults, except—and this is very significant—from that form which follows acute suppurative periostitis.

It is even probable, as showing the influence of these predisposing causes, that the tissues of the human body, so long as they are healthy, possess the power of resisting the action of these germs, perhaps even of destroying them. Burdon Sanderson has shown, with regard to the bacteria producing the poison of septic intoxication, that even if they do enter they have no effect on a healthy organism; and this principle may have a much wider range of application, serving, for example, to explain the susceptibility to scarlatina of patients suffering from traumatic fever.

Pyæmia most frequently attacks large foul and sloughing wounds, particularly if there are imperfectly drained cavities, the contents of which are under high tension. The poison germ gains access to the system all the more easily if the protecting barrier of granulations is often disturbed, or if there are large open venous channels such as those of bone, the walls of which cannot collapse; but it may enter through

the smallest puncture, and, under certain conditions, even this is not required. There are at least two disorders, acute suppurative periostitis and ulcerative endocarditis, in which pyæmia, with organisms present in the blood and numerous secondary deposits, frequently develops and proves fatal within a few days, without there ever having been at any time the smallest breach of surface. How the poison enters is not known; it may be through the respiratory or the alimentary tract. But in the light of Burdon Sanderson's observation, it is difficult to avoid the conclusion that somehow or other it does find its way in, and that either the tissues while in a state of health possess the power of preventing its action, or else that it can only develop its energy under certain conditions, of which the effusion of lymph in connection with bone, and the presence of vegetations on the cardiac valves, may be especially favourable. Just as some patients are able to outlive the exceedingly infective germ of malignant pustule, so, unless there is present some condition favourable to its growth, they may be able to live down the scarcely less virulent one of pyæmia; or the germ may not be able to grow unless the soil is ready for it.

The morbid appearances due to the direct action of the poison differ only in degree from those present in septicæmia, the changes being less marked owing to the comparatively slow development of the poison. All the viscera are congested and cedematous, with here and there small extravasations, especially under their serous coverings; the cut surface is not clearly defined, its structure appearing blurred and confused; the interior of the vessels is deeply stained by the hæmoglobin from the broken-down and disintegrated blood corpuscles, and often there are long, partly decolorised heart-clots. But, except for the presence of microscopic organisms in the blood and tissues, there is nothing special in any of these changes—they are common to all cases of blood-poisoning from whatever source.

Nor does the wound, when there is one, present any characteristic appearance; it may, indeed, show no sign of anything wrong, may seem to be healing in a thoroughly satisfactory manner without a trace of suppuration. But more often suppuration sets in, preceding any evidence of systemic poisoning spreading along cellular tissue and tendon-sheaths, and foul and offensive sloughs make their appearance far away from the seat of injury, with dif-

fuse patches of redness on the skin, or long red lines leading up to swollen and tender lymphatic glands; while, if the bone is exposed, the periosteum can be seen drawing away from it, and the coats of the vessels, especially the veins, are thickened and sodden, with coagula, sometimes of great extent, in their interior. These clots, which by breaking up and being carried off into the circulation give rise to some of the most characteristic metastatic deposits of pyæmia, if of recent formation, are simply loose, dark-coloured masses extending, probably, as high as the opening of the next large branch; but gradually, as they become older, the outer layers become firmer and adherent to the walls of the vessels, while the interior slowly breaks down into a puriform fluid, the result of slow caseous degeneration and disintegration. Only exceptionally, when there is some intense irritant retained in the cavity of the vessels, do the leucocytes collect in sufficient number to form a fluid that may really be compared with pus.

When these clots break down, the débris are carried off by the blood-stream until, meeting with arteries too small to allow them to pass, they become impacted. The immediate effect of this differs according to the arrangement of the blood-vessels. If the branch is a terminal one—that is, its area of distribution having no other arterial supply—local anæmia at once sets in, and passes on either to rapid necrosis with suppuration, or else to slow degenerative changes. If, on the other hand, an influx of arterial blood can take place from collateral sources, one of two things will result—either the circulation will be restored and nothing else happen than thrombosis of the small arterial trunk as far back as its last big branch; or else, the supply not being sufficient for this, and only brought by minute arterioles, the blood from all sides will pour into this small territory without strength of current enough to force its way. From this will follow great congestion, and then, owing to the impaired nutrition of the walls of the vessels, diapedesis, until the whole area becomes a firm, solid mass, dark-red in colour and granular in section—a hæmorrhagic infarction. In pyæmia the source of the embolus is infective, so that suppurative inflammation, sometimes even gangrene, at once sets in, whether there has been infarction or not. Only the appearance differs; in the one case, the surrounding purple zone of congestion being much better marked and the suppuration incomplete, consisting rather in the rapid breaking down

of the tissues than in the formation of a large number of pus-cells. Both varieties are met with in the lungs, but previous infarction never takes place in the liver or the subcutaneous tissues.

As a general rule, when the systemic veins are involved, the metastatic deposits are met with in the lungs, and similarly in the liver when the source of the disease is in the range of the portal circulation. But it rarely happens that the abscesses are confined to these viscera, and not seldom it would seem as if the embolus had traversed the first set of capillaries in the order of the circulation without causing any disturbance, and had then set up secondary inflammations in other organs beyond; and it is no real explanation of this, that Weber has found that purulent fluid can be injected into the veins so fine that it will pass through the lungs and be arrested in the systemic circulation, for the distribution of the abscesses in these viscera is not such as can be explained on merely mechanical grounds. Moreover, there are other circumstances that lead one inevitably to the conclusion that thrombosis, and its consequent embolism, can be only one of the agencies which give rise to metastatic deposits in pyæmia. The secondary affections may be rigidly confined to the same class of tissues as that first attacked; the bones alone may suffer, as in some cases of multiple suppurative periostitis, where, following acute necrosis of the shaft of one bone, others become involved later on and with less severity; or the subcutaneous tissues, or the joints, as in chronic pyæmia, and that which follows scarlatina and other acute specific fevers. It may be that, like rheumatism and syphilis, pyæmia has a certain predilection for certain tissues, or that homologous structures are so intimately associated together by their nutritive changes that it is impossible for one to be affected without the others suffering; but it is quite certain that many of the morbid appearances, in the bodies of those who have died of pyæmia, cannot be explained either on the hypothesis of general systemic infection or of impacted emboli.

Thrombosis, with its attendant embolism, originating at a distance from the seat of injury, will account for some of the morbid conditions. Owing to the alteration in the character of the blood and the serious impairment in nutrition of the walls of the vessels and the surrounding tissue-elements, coagulation readily takes place in some of the smaller capillaries, and spreads backwards and forwards for long distances, es-

pecially in those parts of the body in which extensive hypostatic congestion is found *post mortem*. Slight injuries, perhaps never noticed, will account for many more; the vitality of the tissues being lowered to such a degree that a touch, which would not suffice in the healthy body to cause an abrasion, or a puncture with a hypodermic needle, will often cause an abscess. Even a little over-use of a part will set up extensive suppuration; and perhaps this is the reason why the sterno-clavicular articulation, the knee-joint, and the tendon-sheaths around the ankle, are so often involved. So with tissues that have been injured long before and seemingly have recovered completely: fresh mischief lights up again in them as in the residual abscesses round an old diseased joint, or pneumonia in a lung that has once been inflamed. But even when full allowance has been made for all of these, there yet remain many for which no explanation is as yet forthcoming.

Space is too limited to admit of a detailed account of the various lesions found in pyæmia. The reddened patches on the skin, often fugitive during life, of course disappear after death, only a livid staining, with, exceptionally, pustules and superficial abscesses, being left. In the subcutaneous tissue, and extending thence between the muscles, dissecting them from each other, may be extensive collections of pus without limiting walls, and here and there, especially if there has been bruising or undue pressure, extravasations of blood just breaking down, evidently the result of widespread capillary thrombosis. Pleura, pericardium, and peritoneum may all be full of intensely infective fluid, sometimes consequent on embolic abscesses in the walls of neighbouring viscera, sometimes of independent origin. Every organ in the body, but especially the liver, lungs, spleen, and kidneys, may be intensely congested and riddled with abscesses of all sizes, some the result of embolism, and these conical in shape, with their bases towards the surface and perhaps in the centre of an infarction, sometimes more diffuse and irregular in shape and size. Even the brain and the eye do not always escape. Nowhere around these abscesses is there any evidence of repair—there is nothing but destruction, most advanced in the centre and spreading rapidly all round. The great congestion of the alimentary canal, so common in the pyæmia of animals, is not often met with in man. Frequently, the joints or the tendon-sheaths are distended with thin oily pus, greenish from the pressure of broken-down

blood; sometimes only one is affected, more often several, even when it has not been suspected during life. When very recent, the synovial sac and the cartilages show no great change, but soon they become eroded and detached from the bone underneath, while the pus bursts through the softened and yielding capsule, leaving the joint utterly disorganised. Occasionally, in those forms of pyæmia following gonorrhœa, scarlatina, and the puerperal state, the joint is less acutely affected, and if the patient survive, recovers a surprising amount of its usefulness.

Symptoms.—Pyæmia may set in with a sudden and severe rigor, or its commencement may be insidious, with nothing to mark it but an indefinable sense of anxiety and uneasiness on the part of the patient. The wound may show no change, but this, it must be acknowledged, is the exception; more often the stump or the limb, as the case may be, becomes swollen, red, and exceedingly tender, while the surface of the wound is dry, the discharge thin and offensive, and the granulations ashy-grey. Rigors are rarely absent altogether; there may be only one, and then it is usually of extreme severity, or they may occur throughout at intervals of such regularity as to simulate an attack of intermittent fever; sometimes two or three will occur within a few hours, and then there will be a cessation for days. There is no relation between them and the occurrence of metastatic deposits; often the patient is conscious of when they are coming on; the temperature rises rapidly to 106°, or even higher; the skin on the body becomes hot and pungent, while the extremities are livid and cold; there is an expression on the face of the most intense distress, and the sensation of cold is so extreme that the teeth chatter. Then, after an interval of from a few minutes to half an hour, the temperature begins to fall, the blood makes its way to the surface again, and profuse sweating sets in with a feeling of great exhaustion. Even when rigors are not present, the diagnosis of pyæmia can be made from the great irregularity of the temperature, especially if at the same time there are occasional and profuse sweats.

The aspect of the patient soon changes for the worse; at first he may not feel particularly ill, but soon there is visible on his face an expression of peculiar anxiety and apprehension; emaciation is rapid and extreme, particularly when there is much sweating, the features becoming shrunk and withered, and the complexion assuming a

sallow, often icteric tint, and this independently of any secondary mischief in the liver. The eyes are sunken and surrounded by dusky rings; one cheek may have a bright flush on it, particularly if there is any pneumonia; herpetic vesicles, breaking and leaving painful sores, appear on and round the lips, after the rigors; the tongue becomes dry and brown, the teeth and gums covered with sordes, and the breath, and sometimes the patient's whole body, exhales a peculiar sickening, mawkish odour. The pulse is small, irritable, and too frequent; the respiration hurried and shallow; there may be cough, with rusty expectoration, but this is often absent, even when there is extensive pneumonia; more frequently there is great dyspnoea from intrathoracic effusion; vomiting is not usual, except just at the first, nor is there, as a rule, the profuse diarrhœa met with in the case of animals. The poisoned condition of the blood very early shows its effect on the nervous system; wandering delirium, from which the patient can be roused at first, sets in very soon, and becomes continuous; the skin becomes exceedingly sensitive, the slightest touch giving rise to the most excruciating agony, especially over those places where a slight amount of swelling or induration points to the commencement of some deep-seated inflammation; a typhoid state rapidly follows, and ends in unconsciousness and death. Reddened patches make their appearance here and there on the skin, and change their position from day to day; sloughs and bedsores form with the most extraordinary rapidity, extensive areas of skin becoming gangrenous in twenty-four hours. Swellings make their appearance over joints or muscles; at first white and doughy, they rapidly become soft and livid, until either the skin breaks or they are opened; it seems as if whole sheets of connective tissue melted away into pus. If the joint is left unopened, the capsule gives way, and the abscess may first point a long way off.

If the patient should, happily, survive the first infection, and the secondary complications be limited to the extremities, recovery may take place after a long and exhausting illness, with the limbs more or less crippled. When the viscera are involved, the prognosis is even more serious. Death may take place as early as the fourth day, before rigors or secondary deposits have had time to make their appearance; more commonly the patient dies with some visceral complication about the second week, or from exhaustion from prolonged fever and

suppuration later on. In some exceptional cases the disease is even more protracted, rigors, with sweating and other characteristic phenomena, making their appearance after long intervals of comparative good health. Under these conditions, as Paget has pointed out, there is, in general, less severe disturbance of health and less risk to life, especially in the later stages; moreover, the secondary affections are generally limited to one single structure, such as the subcutaneous tissue of the limbs.

Pyæmia most frequently sets in about the second week after operation or injury; but it may commence at any period, and, as it has been mentioned already, may occur without there ever having been an injury at all, the germ entering the system in some other way, and finding an appropriate nidus for its development.

There is rarely any difficulty about the *diagnosis* of pyæmia; in its acute forms the constitutional disturbance is so severe, and the onset of typhoid symptoms so rapid, that here can be no question as to the existence of intense blood-poisoning. It is harder in the case of the joint-affections which occur as complications following gonorrhœa, scarlatina, and some other diseases. That they are due to blood-poisoning in the wider sense of the term there is no question, but it is not easy to say, at present, whether they would come within the stricter definition of pyæmia. Acute periostitis, affecting the lower end of the femur and causing effusion into the knee-joint, is not infrequently mistaken for rheumatic fever until pyæmic symptoms definitely make their appearance; and acute ulcerative endocarditis occasionally presents a somewhat similar difficulty.

From the foregoing it is evident that the *treatment* of pyæmia must be mainly preventive; when it has once set in, we have but slight influence over its course, though, if the patient survive, much may be done by surgery in the treatment of the local affections. It is so much more prevalent in some years than others, independently of any cause known at present, and is so liable to occur as a complication of diseases of the urinary tract and other parts in which it is almost impossible to prevent decomposition taking place, that it is more than doubtful whether it can ever be stamped out; but a great deal may be done to prevent its occurrence. Pure air, especially absence of overcrowding; rigid cleanliness on the part of everyone concerned; avoidance of anything like tension in a wound, by means of drainage or suitable incisions (probably early incision is the only way to prevent pyæmia

in acute periostitis); perfect rest, so that the granulations of a wound are bruised as little as possible; and careful attention to the activity of the chief excreting organs (which are often seriously interfered with when a patient is suddenly confined to bed) are absolutely essential.

When it has once set in, there is little that can be done; if it occur after amputation, consequent on acute osteomyelitis of the stump, disarticulation has been recommended, and might succeed if it could be done sufficiently early, but much more often the osteomyelitis is itself pyæmic. Division of a vein on the cardiac side has also been advised, and may be successful when the mischief is clearly originating there, but such conditions must be altogether exceptional. Quinine in large doses often has a distinct effect on the temperature, and on the severity of the rigors; but the great indication is to husband the patient's strength in every conceivable way, in the hope that he may be able to live down the activity of the germ, and may avoid visceral complications. Local abscesses should be opened early; no good can arise from leaving them, and often when they are opened they are found to be already much more extensive than they appeared to be. Joints that are affected should be treated in the same way, especially if the skin over them shows a fugitive erythema: in the case of the knee in particular, if a free incision is made on either side sufficiently early under antiseptic precautions and drainage-tubes are inserted, the patient will often regain almost perfect movement, especially in the form of pyæmia following parturition. The same treatment has been adopted in the case of the pericardium, but as the inflammation is nearly always consequent on an embolic abscess in the walls of the heart, a favourable result is much less to be expected.

C. MANSELL MOULLIN.

PYELITIS, or inflammation of the pelvis of the kidney, is not common as a primary disease, but is very often met with as secondary to other renal affections. Amongst its exciting causes may be mentioned the use of turpentine, cantharides, or other stimulating diuretics, the presence of calculi or gravel; again, it is not infrequent in the acute specific fevers, such as scarlatina, measles, &c., and is also due in some cases to tubercle deposited on the surface of the pelvis; finally, it may be produced by cold and chill, or may be due to extension of inflammation upwards from the bladder, such as is met with in gonorrhœa.

rhœa. It is met with in both the acute and chronic forms.

The *symptoms* of pyelitis are often masked by those of the condition on which it depends as a secondary affection; but if we confine our attention to those of the local disease in its simplest forms, we shall find them tolerably distinctive. In the acute forms, there is usually pain of a dull aching character in the renal region of the side affected; this is increased on pressure; sometimes it is paroxysmal when obstruction takes place. There is fever in proportion to the severity of the affection, and the rise of temperature is greatest at night, and often very regular as to the time of its appearance. The disease may commence with a rigor. The condition of the urine, however, gives the most important evidence of all. At first there is great frequency of micturition, and the fluid voided is blood-stained, containing mucus and cells (oval, tailed, angular, or rounded) from the renal pelvis, and actual pus-cells besides. Presently, the pus becomes more abundant and regular in its discharge, unless the ureter becomes blocked; in some cases it is intermittent with tolerable regularity. The urine is acid throughout, unless decomposition extend up to the kidney from the bladder. There is often diarrhœa, except when the bowels are pressed upon by an enlargement of the kidney, which is not uncommon where more or less obstruction of the ureter exists. The most characteristic symptoms of all are the presence of abundance of pus and epithelial débris in the urine, with acidity of the latter; tenderness and pain in the loins, and evening fever with no evidence of disease of bladder, prostate, or urethra.

The *prognosis* of pyelitis, if unilateral and simple, is not unfavourable, but if bilateral the condition must always be considered grave. In simple cases which terminate favourably, the congestion gradually diminishes and the pus with it, the subjective symptoms subsiding at the same time. Too often, however, the inflammation in the pelvis is associated with other graver disease, such as interstitial suppurative nephritis, the course of which determines the result; or pyonephrosis supervenes with all its complications. See PYONEPHROSIS.

The *treatment* of pyelitis is essentially the same as that for NEPHRITIS.

ARTHUR E. BARKER.

PYELONEPHRITIS, or inflammation of the pelvis and substance of the kidney, has been so frequently met with associated

with serious surgical conditions of the lower urinary passages, for which operations have been required, as to have been often called 'surgical kidney.' This is an unfortunate misnomer, tending as it does, on the one hand, to suggest that the disease is not met with except as the result of surgical operations, and on the other that, when renal disease supervenes in the course of some condition lower down, it is always necessarily pyelonephritis. Neither of these propositions is true: the disease is often met with independently of surgical operations; and when the latter, or the conditions requiring them, are followed by renal mischief, it is often of a kind quite distinct from pyelonephritis.

If we take a typical case of the affection, its course will be about as follows. Usually, owing to some obstruction to the flow of urine from the bladder, whether it be from stricture, enlarged prostate, villous growth, or other cause, the bladder is kept in a state of chronic distension, and becomes hypertrophied. If the obstruction persist long enough, dilatation of the ureters and pelvis of the kidney is very likely to take place, owing to the pressure of the secretion endeavouring to reach the bladder against the resistance of the hypertrophied organ. And this effort, again, on the part of the kidney is probably a source of some irritation to the parenchyma of the organ, predisposing to, if not actually initiating, inflammatory changes in it. The bladder, further, is predisposed to catarrhal affections by the chronic retention of urine in it. If, now, any acute cystitis is set up, as the result of the introduction of some ferment into the retained fluid (either on a foul instrument or by the spread of decomposition up the traces of urine and mucus remaining in the urethra during the 'overflow' of bad retention, or by other causes), we have almost inevitably a spread of the septic process sooner or later into the dilated ureter and pelvis, and from this into the straight tubes of the gland, already predisposed to inflammation by the prolonged irritation. As a consequence of this, free suppuration and even ulceration is set up in the calyces and pyramids until, in many cases, the latter are almost completely destroyed, and the whole organ is converted into a foul abscess.

The disease is, however, produced in other ways. Thus, the presence of a calculus or calculi may cause ulceration in the calyces, and suppurative inflammation in the substance of the gland. But this cause alone rarely produces the worst forms of the

disease. It may be the result of breaking down of tubercular deposits in the kidney or its pelvis. It may also follow gonorrhoeal inflammation of the urethra and bladder without retention; but in this case, too, destructive inflammation is not often met with.

The appearance of a kidney affected with a considerable amount of acute pyelonephritis is remarkable. The organ may or may not be enlarged; it will in recent cases strip readily out of its capsule, except at certain points at which more or less firm adhesion has taken place. At these spots the colour of the cortex will be altered, and may range from purple to ash-grey or the colour of pus. In the latter case, the consistence of the affected spot will be diminished, or it may even be diffuent. In addition to this, the softer areas are usually somewhat bulged outwards, giving to the whole outline of the organ a peculiar irregularity. On section of the kidney from its great curve to the hilus, each bulged discoloured portion will be found to correspond to a suppurating tract, reaching from the apex of a pyramid to the surface. In many cases the affected pyramids are almost completely destroyed, and the whole organ and its pelvis are converted into a foul, grey, sloughing cavity, more or less crusted with phosphatic deposits.

The *symptoms* are usually severe pain in the loins, aggravated by pressure over the kidney through the abdominal wall. Then there is high fever, especially at night, often ushered in and accompanied by rigors; there are also thirst and anorexia. Objectively, we have a hot flushed skin and an expression of much anxiety, and great frequency of micturition. There may be slight fulness in the renal region, to be felt with the hand. The urine passed is not so abundant as usual, and is loaded with pus, but is still acid in ordinary cases, if taken fresh from the kidney. Often, however, during its sojourn in the bladder, it decomposes, and is passed alkaline. If, however, the bladder be washed out, and then a little of the secretion be collected fresh, it is acid, and may possibly be inoffensive to the sense of smell.

The *treatment* of this condition is by no means satisfactory: still, something can be done. In the first place, all sources of irritation in the lower urinary tract must be removed as far as possible. Obstruction should be relieved as completely, but with as little violence to the parts as may be. The bladder should be washed out carefully with an antiseptic fluid, such as a two-grain

solution of sulphate of quinine or weak Condy's fluid. The loin or loins may be cupped and fomented, if there be much tenderness and check to the secretion of urine. The diet should be very light, consisting chiefly of milk. Quinine should be prescribed internally, and tr. ferri perchlor. Stimulants must be given in very asthenic cases, but should be used cautiously. Complete rest of body and mind should be secured as far as possible, and the surface of the body be kept warm, and protected against alternations of temperature. In certain cases of tubercular disease, or where renal calculi or gonorrhoea are at the root of the condition, it may be proper to perform nephrotomy if the patient's general health be fairly good.

The *prognosis* in cases of double pyelonephritis is extremely bad. In such cases, we usually find the other conditions lower down so severe as to be themselves very dangerous to life, and the additional disease of the kidneys renders them almost necessarily fatal. When one organ alone is suppurating freely there is a better prospect, provided the other conditions are not too far advanced. One kidney may be thus more or less completely destroyed, and, on the inflammation subsiding, nothing but a small mass of cicatricial tissue be left in its place, the opposite kidney taking over the double task, and hypertrophying accordingly.

ARTHUR E. BARKER.

PYLORUS, Operations on the.—In considering this subject it is to be noticed, first, that hitherto these operations have been undertaken chiefly for the removal of neoplasms of the pylorus, usually varieties of carcinoma—i.e. scirrhus, colloid and medullary cancer. They have also been employed in a few cases for other conditions, such as simple ulcer, or stenosis from various causes, or for the establishment of a permanent opening of the duodenum, for the purpose of introducing food in desperate cases of gastric cancer. But, should they be limited to selected cases of malignant disease of the pylorus alone, there is still a large field of usefulness open. Cancer of this part is a comparatively common affection, and as it is a common, so is it a hopeless condition, unless the diseased mass is early removed; and not only so, but the suffering entailed on the patient is most distressing. In the matter of pain there is certainly some variation, little being complained of in certain cases, though in others it is most severe. But, apart from this, there is the distress of

hunger not to be appeased, of distension of the stomach, and, often, of persistent vomiting. At the best we can only look forward to slow, inevitable starvation for our patients, until extreme weakness and perhaps anæmia, due to repeated bleedings from the new growth, put an end to a miserable existence.

It would be foreign to the scope of this article, to enter into the details of diagnosis of disease of the pylorus and the resources of medicine in its palliative treatment. It must be assumed that these points are understood, and that the cases are taken up by the surgeon when the physician admits his powerlessness to do more. This leads us first to the consideration of the operation for removal of the pylorus.

This was first performed on April 9, 1879, by Péan of Paris, whose description of the procedure is too imperfect for the reader to estimate safely the probable cause of its want of success. It was next performed by Rydygier of Culm on clearly defined principles, but the patient succumbed from shock twelve hours after the operation. Billroth followed next with a success in the case of a woman of forty-three, who was alive and well some months after. The next two operations were also performed by Billroth, but both patients died from their effects. Then comes a most successful case by Woelfler, whose patient was alive and well four years afterwards. Since then, the operation has been done many times, with varying results, by several Continental surgeons. In this country but little has been attempted in this direction, the only three cases recorded having proved fatal, and we are obliged to turn to the German surgeons for statistics of the procedure so far. Thus, Billroth and his assistants have removed the pylorus eighteen times with ten deaths, Gussenbauer five times with four deaths, Rydygier five times with two deaths, Czerny four times with two deaths. On the whole, up to August 1885, the pylorus has been resected at least 82 times, according to Kramer. Of these 72 suffered from carcinoma, the rest from stenosis—the result of ulcer of the pylorus. Of the first 72, 55 died; 17 recovered; and among the remaining 10 we find 4 recoveries and 6 deaths. These statistics teach but little, except so far as the results in the hands of individual operators can be compared. They are introduced here as indicating the extent to which this branch of surgery has already developed, and as generally suggestive of the gravity of the procedure.

But though a most formidable operation, both on account of the difficulty of its performance and the high rate of mortality which has hitherto attended it, it has been justified on the following grounds:—First, the inevitably fatal character of the disease for which it is undertaken, and the suffering entailed thereby. Secondly, the disease, if cancerous, remains for a long time localised to the immediate neighbourhood of the pylorus. Thus, out of 542 cases dying of cancer of this part, 223 had no secondary deposits anywhere. Thirdly, it is slow to contract adhesions to adjacent parts. Finally, it has been shown, by post-mortem examination of a large number of cases dying of malignant disease here, that it does not commonly extend to the duodenum or neighbouring glands before it has produced fatal stenosis.

Admitting, then, that for certain patients, and in the hands of skilled surgeons, this operation is justifiable as holding out a sufficiently good prospect of temporary and perhaps permanent relief, we have briefly to consider the selection of cases and the preliminary preparations necessary before operation.

In the first place, the patient's age is a matter of more importance here than elsewhere, in view of the length of the operation and the vital region in which it is performed. The same may be said of the general health. Old and weakly individuals, therefore, should not be subjected to the risk, and, with younger people, their general state should be good to justify the operation; which is as much as to say that, if anything is to be done for them, they should not be allowed to run down to the last stage of weakness before the surgeon is asked to interfere. The subjective and objective symptoms should be distinct, and especially the tumour, which, moreover, should be freely movable in all directions—i.e. without adhesions to surrounding parts. Slight adhesion to the abdominal wall may not, perhaps, quite contra-indicate the operation in cases otherwise favourable, inasmuch as the adherent portion of the parietes may be excised with the growth. Cases, again, in which there is great chronic dilatation of the stomach, appear unsuitable for operation, unless the condition can be overcome by preliminary treatment. A dilated stomach, after such an operation, almost inevitably assumes a position in which its walls act like a valve to the new opening, and prevent all passage of food through it, as in Billroth's second case.

All these points should be closely examined into with the help of careful palpation of the abdomen under chloroform; and in cases in which there may be doubt on one point or another, but which appear generally suited for operation, an exploratory incision through the abdominal wall is quite justifiable, in order to examine the relations and condition of the growth with perfect accuracy. If these things appear in closer inspection to contra-indicate interference, this opening may be closed without further action.

When it is decided in any given case to proceed to excision of the pylorus, certain preliminary measures have been shown by experience to contribute to a favourable result. Among these, the careful washing out of the stomach with tepid water stands first in importance. This is effected by means of an ordinary soft rubber tube passed into the stomach, and attached to a funnel at the other end. Through this about a quart of tepid water is passed into the organ, and then allowed to syphon out again with the funnel held at a lower level. This is repeated over and over again, until the water returns clear. This treatment should be begun several days before operation, and should be done two or three times each day, and finally, about an hour before the operation is begun, the organ should be washed out with a solution of salicylic acid in water (1 in 1,000). It is an extremely unpleasant procedure for the patient at first, but is better tolerated with practice. In view of the gravity of the operation, neither it nor any other detail necessary for the absolute cleanliness of the field of action should be omitted. The bowels should also be carefully unloaded by means of high-reaching enemata, repeated two or three days beforehand.

As to the operation itself, it is first necessary to remark that the position of a cancerous pylorus may vary greatly. It has been found to the right or left of the umbilicus, and even as low down as Poupart's ligament or the symphysis pubis. The position of the ventral incision will therefore vary accordingly, but it usually lies between the navel and the margin of the ribs, and parallel to the latter on either side. Some operators however prefer the linea alba above the umbilicus. The direction, in the first case, will be modified more or less by the exact situation of the diseased mass, which is the real determining consideration. The incision in the abdominal wall is made layer by layer, until the serous lining is reached, but the

latter is not divided until all bleeding is completely arrested. In severing the attachments of the diseased mass, both the greater and lesser omenta are divided, but always to as small an extent laterally as possible. One of the greatest dangers after operation is sloughing, either of the gastric or duodenal margins of the united wound, or of the walls of the colon, due to disturbance of nutrition or innervation as the result of damage to the greater or lesser omenta, and this has to be guarded against by every means possible. Every effort should also be made to spare the pyloric, gastro-duodenal and gastro-epiploica dextra arteries and their branches, consistently with the thorough removal of the growth, and any glands in the neighbourhood which may excite suspicion. In dividing the stomach and duodenum, bold strokes should be made with a very sharp scissors, to ensure even-cut edges suitable for accurate apposition. Various clamps have been suggested, from time to time, to fix the borders of the viscera during the stage of stitching; but if Woelfler's suggestion (see below) be adopted—i.e. to divide each viscus only partially, and unite the portions thus divided before proceeding to complete the excision—nothing of the kind will be required.

Operation.—In an ordinary case, in which the pylorus maintains very nearly its normal position, an oblique incision is made parallel with the right costal margin, and between this and the navel. This incision should be about 11 centimètres long, = $4\frac{1}{2}$ inches, about one-third of it being to the left of the linea alba. If the tumour be to the left of the middle line, a corresponding incision is made parallel with the left costal border. Either of these gives much freer access to the affected region than the incision in the linea alba, practised in several cases. At first the knife is only carried as far as the peritoneal lining, without dividing it, and before the membrane is opened, every bleeding point is controlled until the wound is dry. Then the serous lining is divided, the cavity of the abdomen opened, and a most careful examination of the condition of the pylorus is made. For the present, at all events, it is well to adopt the rule that extension of the growth either to the colon, the pancreas, or the duodenum, contra-indicates completion of the operation; and if such complications exist, further exploration should cease and the abdominal cavity be closed, unless digital dilatation of the pylorus be considered justifiable (*vide infra*).

But where the growth is limited to the immediate neighbourhood of the pylorus and lesser curvature of the stomach, we proceed by drawing it, with a broad many-toothed vulsellum-forceps, as far as possible out of the parietal wound, and commencing its isolation. First, the omentum is separated for a certain limited distance along the greater curvature of the stomach, having been tied in small portions and divided between the ligatures. Then the lesser omentum is similarly severed, but also to as limited an extent as possible. All this time the exposed viscus is covered with thoroughly aseptic napkins, wrung out of warm carbolic or salicylic acid solution. When fully isolated above and below, a napkin or flat sponge is slipped under the diseased portion, and this protects the abdominal cavity from the entrance of blood or fluids from stomach or duodenum, when divided. The removal of the growth and subsequent union of the cut edges is, consequently, practically an extra-peritoneal operation. One of the most difficult problems presented by the whole procedure now offers itself—namely, how to divide the sound tissues on either side of the growth, so that the very much larger lumen of the stomachal opening may be best adapted to the smaller duodenal one, and how best to unite them. This is done in various ways, according to the shape of the growth. The mode now described is that followed by Billroth in his later cases, and embodies slight modifications of the method pursued in his first successful one. These modifications had shown themselves to be of great value first in the hands of Woelfler, from whom they emanated.

In the smaller end of the stomach an incision is first made with one or two bold, steady strokes of a scissors downwards and obliquely from left to right, dividing both sides of the organ at once, but only for about two-thirds of its depth. This incision will lie about three-quarters of an inch from the limits of the growth, and in sound tissue. The stomach is now freely opened above, but is still attached to the pylorus below. The edges of the stomachal wound are now brought carefully together with a double row of stitches, according to Czerny's method. This consists in introducing first one row of fine carbolic silk threads, dipping through the serous and muscular coats of the organ at about a quarter of an inch from either edge of the wound in its walls, and coming out on the cut surfaces without including the mucous coat. When drawn tight, the

edges are brought together by their serous surfaces alone. These threads are set apart about a tenth or an eighth of an inch apart from one another, and when tied are cut short at once. They are then succeeded by a second row a little farther off from the edge of the wound, each stitch lying opposite an interval between those of the first row, and entering and leaving the serous and muscular coat without including the mucosa. These are not cut short at present, as they serve to hold the stomach steady after its complete division. This is now done with the scissors as before, and the resulting opening ought now to correspond in size with the lumen of the duodenum. The latter is now half cut through from above with the scissors, by one bold stroke passing obliquely from left to right as in the case of the stomach, and clearing the border of the growth by about three-quarters of an inch.

Steadying the duodenum by the still attached mass held in a vulsellum-forceps and the stomach by the ends of the 'occlusion sutures' not yet cut short, the operator now stitches the upper divided portion of the duodenum to the upper part of the reduced orifice in the stomach. The stitches here may be introduced as in the case of the stomach, or may be begun on the inner aspect of the bowel for its posterior third, by thrusting the needle between the mucous and muscular coats, then through the latter and the serous then through the serous and muscular coats of the opposite border, and so on to the edge of the second cut surface again where the thread is tied. The knot in this case lies within the bowel instead of between the serous surfaces, but the effect is the same as far as the apposition of the latter is concerned. This mode of suturing the ends is only applicable to about the posterior third of the circumference of the bowel. When this has been accurately united to the border of the stomach, the remaining half of the duodenum is severed and the growth is now completely removed. The rest of the stitching is now finished with the Czerny suture, as above described, introduced from the serous aspect. The two cut ends of the bowel are now accurately united on their serous aspect, and should be quite water-tight if sufficient care has been taken to place the stitches at equal distances and to tie them evenly. The partial division of the viscera, just described, may be done either from above or below, according to the shape of the growth, but the former method has been found to give the best

result as to the future shape of the stomach. In either case, the reduction in size of the stomachal opening by stitching (*Occlusions-naht*) precedes the further steps of the operation. It is almost needless to remark that, throughout the whole procedure, the field of operation must be constantly cleansed from blood and the visceral secretions with soft carbolised sponges, besides being protected from every chill; all bleeding, too, must be at once arrested with clip-forceps.

The subsequent steps of the procedure are simple. After a final cleansing of the whole field of operation, the united ends of the viscera are carefully replaced in the abdomen, and adjusted so as to favour the directness of the opening of the stomach into the duodenum; then, the abdominal cavity is closed in the usual manner, so as to bring the serous surfaces of the parietes into contact with one another.

The *after-treatment* of the patient is often a matter of much difficulty. A careful study of the articles of diet best borne by the stomach before operation is of the greatest importance. At first some easily digested fluid is given, iced and in very small quantities, while peptonised and alcoholic enemata are administered at regular intervals. Then, by degrees, there is a cautious return to the ordinary articles of diet. Opium may be required, but should not be given unless urgently called for, as it may produce nausea or even vomiting, which would be most injurious. In some of the successful cases it is remarkable how little interruption there was to complete and rapid recovery; in one (Woelfler's), the patient was able to eat meat from the tenth day onwards, and in Billroth's first case, a beef-steak was eaten on the twenty-first day with no ill effect.

Several variations in the method of suturing the bowel might be mentioned here, but the writer has thought it wiser to describe what may be taken as the typical method only, lest any confusion should arise. In addition to the last-mentioned operation of pylorotomy, another has to be mentioned here which will probably take its place in the future, in many cases of disease of this part.

DIGITAL DILATATION OF THE PYLORUS is an operation designed and practised first by Prof. Loreta of Bologna, in September, 1882. Hitherto it has been employed only in cases of non-malignant stenosis, and here it appears to have done good service. The operation consists in cutting down upon the pyloric end of the stomach,

with all the preliminary precautions mentioned as necessary for pylorotomy, drawing a portion of the viscus into the parietal wound, and incising it sufficiently to admit the forefinger. The latter is then thrust with a rotatory motion through the narrowed pylorus, dilating as it goes; then, the left forefinger is similarly insinuated along the first, and both are separated until a dilatation of three inches has been effected. The stomach wound now is sutured in the usual way, and then (with due care as to cleansing the parts around) the abdomen is closed.

So far, this operation has been performed six times. Three of the patients recovered and were much benefited, in a fourth the result is doubtful, while two died as the result of the operation. The time consumed in the whole procedure compares very favourably with the records of other operations in this region. In Loreta's four cases the average duration was under thirty-three minutes, the longest fifty minutes.

GASTRO-ENTEROSTOMY is an operation which was first performed by Woelfler in September, 1881, as an alternative to pylorotomy in certain cases. Indeed, it appears not improbable that it may supplant the latter measure to a large extent, in view of the great tendency to recurrence after excision of the pylorus and its great risks, the newer operation giving much relief and being easier of performance and far less dangerous, although of course only palliative. Without entering further into this question here, the operation may now be briefly described.

In the first place its object is to establish an opening between the stomach and small intestine, as high up in the latter as possible, in order that the contents of the former may find their way through the digestive tract, hitherto blocked by the disease of the pylorus. If this opening is once established, the food leaving the stomach becomes mixed with the secretions of both liver and pancreas in the bowel, and the processes of digestion and assimilation are performed as usual, the patient being much relieved until generalisation of the disease, if malignant, terminates life. If, on the other hand, the operation is performed on account of chronic ulcer of the pylorus, with or without stenosis, the rest given to the part, and the improvement in general nutrition, may lead to repair and cure of the condition.

The preparations for the operation are identical with those for pylorotomy, described above. The same may be said of the incisions until the stomach is reached.

From this point the procedure is very simple. First, the stomach-wall is drawn out of the wound and so held. Then, a loop of small intestine is caught as near to the duodenum as possible and also made to protrude from the abdominal opening. Here, it is emptied of its contents by being passed through the fingers, and is kept so by two ligatures passed through its mesentery on either side of the emptied portion and tied lightly. It is then incised along its free border for an inch and a half, and this wound is carefully cleansed. A corresponding opening is made towards the pyloric end of the stomach at some small distance above its great curvature, so as to avoid the larger vessels. When all bleeding has been controlled and the parts cleansed perfectly, the two openings are united on their serous surfaces by Czerny's suture in the usual way, the posterior edges being stitched first. To avoid a possible 'kink' in the intestine at the point united to the stomach, it is well to stitch the bowel to the latter for about an inch or so beyond either end of the orifice, in the same way. Nothing now remains but to cleanse the whole field of operation, and to close and dress the abdominal wound in the usual manner.

DUODENOSTOMY, or the formation of a permanent artificial opening into the duodenum through the abdominal wall, is another alternative to pylorotomy, which need only be briefly mentioned to be condemned. It has been performed three times in desperate cases of cancer of the pylorus, but has proved fatal in each. It is hard to see any grounds for its justification, especially since in gastro-enterostomy we possess an operation as easy of performance, not more dangerous, and which re-establishes the communication between the stomach and small intestine so that the patient may be fed in the usual manner by the mouth.

The operation consists in cutting down upon the pylorus in the way mentioned above, then drawing the anterior wall of the duodenum into the wound and stitching it there by its serous and muscular coats alone, as in gastrotomy. When adhesion has taken place all around after a day or two, the bowel is opened and the patient is fed through the orifice.

In **JEJUNOSTOMY**, which has lately been brought under notice, we have another alternative to pylorotomy. It has the advantage over duodenostomy that it is easier to perform in every way. But, beyond this, it is difficult to see how it is likely to come much into use so long as we

have gastro-enterostomy to replace it. In the report of an interesting case brought before the Clinical Society by Mr. Golding Bird, in November, 1885, the method of procedure was detailed, as well as some recommendations for the after-treatment of the patient; and, in the debate which followed the reading of this case, the whole question was fully discussed. But though the patient did not die as the result of the operation, but in consequence of a regrettable accident, the impression left upon the mind of the writer is that the operation has little to recommend it, so long as gastro-enterostomy gives such promising results as hitherto in the very distressing class of cases in which it is employed. The mode of operating for jejunosomy is essentially the same as that for duodenostomy just described, except that a coil of the jejunum is opened instead of the duodenum.

ARTHUR E. BARKER.

PYONEPHROSIS, or the distension of the pelvis and body of the kidney with pus, is a common affection. Like hydronephrosis, it is usually unilateral. In the mechanism of its production, too, it resembles the latter condition in many ways, with the element of inflammation superadded. This inflammation presents itself in one or other of the many forms of **PYELITIS**. Again, a hydronephrosis may be converted into a purulent collection by injury, such as a strain or blow upon the sac, or after puncture for its evacuation. Further, a penetrating or contused wound of the kidney may lead to the formation of pyonephrosis.

The *objective symptoms* are almost identical with those of **HYDRONEPHROSIS**, and need not be separately described. It has been noted, however, that though the latter may enlarge until it has transgressed the middle line of the body, such is never the case with the purulent collection. An examination, too, of the urine will often furnish extra evidence. Thus, we are, in many cases, able in this disease to demonstrate pus in it, when there is no evidence of any morbid condition in bladder or urethra. Such pus is met with in acid urine, and is not usually constant in amount. Indeed, on some occasions it is entirely absent, often to re-appear suddenly in abundance, with perhaps some relief to the general symptoms of distension, but with increased frequency of micturition.

The *subjective symptoms* here are those again of hydronephrosis, with, in addition, some rise of temperature in many cases.

This is usually regular in its appearance very evening, the morning temperature being normal as a rule. In some cases, however, where renal colic accompanies the onset of the condition, there may be a rigor with general febrile disturbance. But the diagnosis between hydro- and pyonephrosis is always made quite easy by incision and aspiration with a fine needle, a procedure easily carried out and destitute of risk, if performed on the lines already laid down under HYDRONEPHROSIS.

The treatment of pyonephrosis is not always the same. Aspiration, often repeated, may be at last successful in relieving the tension, but is very rarely so. It is justifiable, too, that it may give rise to further complications if not employed with great care. Thus, septic matter may be introduced into the sac, with the consequent abscesses, or again, the sac, being frequently perforated by the needle, may yield at one point in spot and the pus escape into the perinephral tissues, so forming a lumbar perinephral or a psoas abscess.

The best treatment for ordinary cases is in doubt, in the first place, free antiseptic drainage at the point of election behind. See NEPHROTOMY. If this does not result in the final shrinking and closure of the sac, and the patient suffer much from the prolonged discharge with its attendant discomfort and risks, which are often great, NEPHRECTOMY should be resorted to. It should not be forgotten, too, that prolonged suppuration here may lead to amyloid change in the internal viscera; and that a change of that kind affecting the opposite kidney would, in this case, be more usually grave, in view of the damaged condition or perhaps complete destruction of its fellow. But besides this, the opposite kidney may, in some cases, be damaged by a reflex irritation due to the passage of pus from the diseased side through the bladder, when the drainage through the ureter has released the obstruction to the bladder, as it sometimes does. As this pus, in spite of every precaution, often becomes collected in the sac, during the months through which the renal fistula discharges while the patient is up and about, we need not be surprised to find that it produces cystitis in some cases, and the secondary changes just referred to in the opposite kidney, which has hitherto been quite sound. This is a strong argument against allowing a pyonephrosis to remain too long through the loin. If there is evidence that the other kidney can do the work of the economy, and the patient's general condition do not contra-indicate it, VOL. II.

nephrectomy will be the proper treatment in many cases.

In the *prognosis* of pyonephrosis we have to consider the immediate prospects of the patient, and the remote. The first varies much with the cause of the purulent accumulation. If it have formed slowly—e.g. from the gradual closure of the ureter due to inflammation of the pelvis—the immediate outlook is not grave. The collection may only give rise to distress from its bulk, and, until this becomes extreme, little is complained of, and the febrile disturbance may be but moderate. But when the condition is caused by the sudden blocking of the ureter of a kidney actually suppurating, there is rapid distension, with far greater disturbance of the parts around, and this, with the usually greater fever, is a distinct source of danger calling for speedy treatment. Eventually, the remote dangers in both instances are the same. First among these is rupture of the sac, with outpouring of its pus. If this take place into the peritoneal cavity, the result is a necessarily fatal peritonitis. Fatal empyema is also occasionally produced by bursting of the sac into the thorax, or abscess of the lung, but recovery has been seen even after these complications. Less dangerous, but still formidable, is rupture of the sac into the adherent colon or small intestine, with the thorough evacuation of the pus, but most probably with acute inflammation of the bowel sooner or later. If the collection burst into the perinephral tissues the pus may rapidly form a large extra-renal collection, which again may rupture in various directions. See PERINEPHRITIC ABSCESS. The most favourable termination of all is very rarely seen—namely, the giving way of the obstruction and permanent drainage of the pus into the bladder, or the ulceration of the sac into the ureter itself at a point low down, where it is expanded and flattened out, being pressed upon by the tumour; in either of these ways a spontaneous cure may be brought about, but the chance of such an event is exceedingly remote.

But, without rupture in any of these directions, a pyonephrosis may become dangerous from its gradual enlargement, with pressure upon important parts, and interference with their functions. This, together with the consequent fever, often gradually leads to a state of marasmus, which eventually terminates the patient's life.

RADIAL ARTERY, The.—I. *In the Forearm*: from opposite the neck of the radius to the styloid process of the radius. The artery runs down superficially for most of its course, but overlapped above by the supinator longus muscle.

In front are the cutaneous structures only, but the supinator longus overlaps it above. *Behind*, it rests on the tendon of the biceps, the supinator brevis, the pronator radii teres, the flexor sublimis, the flexor longus pollicis, the pronator quadratus, and the radius. The radial nerve approaches it on the outer side in the middle third of its course. Venæ comites accompany it.

LIGATION.—1. In the upper third: Support the limb in the position of abduction, with the forearm supinated. Make an incision in the line of the artery, two inches long, avoiding the cutaneous veins. Cut through the cutaneous structures, and find beneath the deep fascia the inner free edge of the supinator longus; flex the forearm slightly, draw the relaxed supinator longus outwards, expose the artery, and, after separating the venæ comites, pass the needle from without inwards.

2. In the lower third: Place the arm and forearm as before. Make an incision in the guiding line of the artery, or on the radial side of the flexor carpi radialis, for a distance of two inches, ending not lower than one inch above the wrist. Cut through the cutaneous structures, raise the deep fascia on a director and incise it, find the artery and, after separating the venæ comites, pass the needle from without inwards.

3. In the middle third: The radial nerve is found on the radial side of the artery; hence care must be taken to avoid it.

II. *At the Wrist.*—The radial artery lies in the front of the forearm, and passing downwards below the level of the styloid

process of the radius, it winds backward beneath the three extensor tendons of the thumb, to reach the palm of the hand between the first and second metacarpal bones. In this course it can be felt, and could be tied, between the extensor primus and extensor secundi internodii pollicis tendons. JAMES CANTLIE.

RADIUS, Dislocation of the.—The head of the radius may be displaced in three directions—viz. *forwards, backward or outwards.*

DISLOCATION FORWARDS is the most frequent, and it may be partial or complete. Usually, it is caused by a fall on the palm, occasionally by a direct blow or fall on the outer and back part of the elbow, and in children by dragging them by the arm. The writer saw, in 1880, a partial dislocation forwards, caused by a nursemaid angrily dragging a crying child up stairs to bed, when the parents were out. The *symptoms* are semi-pronation and inability to flex the arm beyond a right angle, owing to the head impinging against the front of the humerus. During extension the head comes forward, and can be felt, and often seen beneath the skin, whilst behind and below the external condyle, a depression may be felt in the situation from which the bone has been displaced. Much difficulty has occasionally occurred in reducing this dislocation, owing perhaps to a portion of the orbicular ligament intervening, but more often the bone may be reduced with ease, and then has a tendency to relaxation. Reduction is to be effected by extension at the wrist, whilst the thumb is pressed on the head, followed by flexion. Afterwards, the limb should be put up in a rectangular anterior splint, and, if there is a tendency to relaxation, this position should be maintained for a month or six weeks, and then passive motion be gradually commenced. In cases where the dislocation has remained unreduced, a ne-

joint is formed in front of the humerus, the head of the radius becomes partially absorbed, and the power of flexion gradually decreases.

An injury produced by dragging young children by the arm, causing pain, protraction and semiflexion, has attracted the attention of several surgeons, and doubt has been expressed whether the injury was at the elbow or wrist, Goyrand having suggested that it was due to displacement of the triangular cartilage in front of the carpal extremity of the ulna. J. H. Hutchinson, in experiments recently undertaken upon the bodies of infants, has found that, under strong traction during supination, the head of the radius slips below the orbicular ligament, and that semiflexion and protraction will cause the ligament to assume its natural position, with a click. This displacement of the orbicular ligament, he believes to be the lesion usually present in these sprains.

DISLOCATION BACKWARDS comes next in point of frequency. It may be caused when the arm falls on the palm when the forearm is only pronated, by direct injury to the joint of the arm, or by twisting the forearm into a state of over-pronation. The forearm is semiflexed and pronated; supination and flexion are painful; the head of the bone may be seen and felt behind the external condyle; and a depression can be felt below the external condyle, whence it has escaped. Fracture of the external condyle is sometimes a complication. Reduction should be effected by extension and pressure, after which a rectangular splint should be applied, and a pad pressed over the back of the head of the radius. During extension the head is liable to be relaxed. W. Allen has related a case where, as a result of backward dislocation in early life, the head of the radius released from pressure grew one-quarter of an inch, and the external condyle half an inch.

DISLOCATION OUTWARDS is very uncommon, and, according to Hamilton, is secondary to dislocation forwards. The head projects beyond the external condyle, and is felt to rotate during pronation and supination. It should be pressed into place during extension, and a rectangular splint afterwards used, with a pad to keep the head from again slipping out.

R. CLEMENT LUCAS.

RADIUS, Fracture of the.—Fractures of this bone, unassociated with fracture of the ulna, are, if we exclude Colles's fracture,

rare. They may, however, occur through the neck, shaft, or lower end.

Fracture of the *neck* is much more rare than some have believed; yet there are now many instances on record in which it has been proved by dissection. The writer has recorded an instance in which, during an operation for the removal of the upper end of the radius in what seemed to be a case of old unreduced dislocation of the head forward, locking the joint, he found the real condition to be that of comminuted fracture of the head and neck of the bone, with large heaping up of callus between it and the ulna. In a second case, that of a little girl aged ten, the daughter of a surgeon, there was, after she had fallen upon the hand, very plainly marked crepitus, apparently close beneath the skin, and at the junction of the neck with the shaft of the radius; and no movement of the head of the bone occurred when the shaft was freely rotated. There was no displacement. All the symptoms disappeared at the end of a month, during which the arm had been kept in a rectangular splint. There was no loss of movement.

The *symptoms* of fracture of the neck of the radius are non-movement of the head when the shaft is rotated; preternatural mobility of the upper fragment when grasped between the finger and thumb; crepitus and pain on attempted supination. In the first of the two cases related above, the injury presented all the appearances of dislocation of the head of the radius. The only *treatment* required is the use of a rectangular splint for the arm and forearm, to maintain rest. Passive movement should be commenced at the end of three weeks, to be, of course very gently, used till union is firm, and steadily employed while stiffness remains.

When fracture occurs at any point between the insertions of the biceps and the pronator teres, the upper fragment, as Mr. Lonsdale has pointed out, will tend, under the action of the biceps (and, it may be added, of the supinator brevis), to be strongly supinated, while the lower will be left entirely to the pronators. Should union in this position be allowed to occur, even though the fragments are placed end to end, the rotation of the one or the other will entail complete loss of the movement of supination. To avoid such a result, the limb, in this particular fracture, must be placed in a position of supination on a rectangular splint, applied to the posterior or dorsal aspect of the arm and forearm. Passive movement of pronation and supina-

tion should be commenced in about a month, and the splints may at the same time be discontinued, the arm, however, being kept in a sling.

Fracture of the radius and ulna together is of frequent occurrence at all ages, but especially in children, in whom it results from falls on the limb. In adults, it is generally the result of direct violence, as by the passage of a wheel, or by a heavy blow. Malgaigne records a case in which it was caused by muscular action (while the patient was digging). The fracture is most often seen at the junction of the middle with the lower third of the bones, or above this point. The bones are usually broken transversely, and at the same level; but the radius may give away a little higher up than the ulna. In children, in whom the fracture is often incomplete (greenstick), displacement is very slight, or may present itself as a mere bend, not easily observed in the fat limbs of infants. Thus, care must be taken that this injury is not overlooked. In adults, considerable riding of the ends may occur when the fracture is oblique. The nature of the injury is generally indicated by deformity, mobility, and crepitus.

It is difficult to secure a good result after this fracture, on account of the strong tendency that exists to displacement by the supinators and pronators of the forearm, as described above. To prevent this, the limb should be fixed in a position of supination on a rectangular splint, applied to the posterior aspect of the arm and forearm; and, for an extra precaution, a short anterior splint should be applied to the forearm, with a narrow pad placed over the interosseous space to maintain, as far as possible, the proper interval between the bones. The limb must be supported in a firm sling. In adults, movements of supination and pronation should be gently employed every other day or according to circumstances, at the end of a month; but the dorsal splint should be continued, so as to maintain supination, for at least five weeks. In children the period of treatment may generally be reduced to three weeks.

Fracture of the radius and ulna, at their *inferior extremities*, is occasionally seen. The nature of the injury is usually clearly indicated by mobility and crepitus, and the tendency for the deformity to return when extension is discontinued; but when the fracture is within an inch of the articular surfaces, the aspect of the limb may very closely resemble that of dislocation of the carpus backwards. The latter accident,

however, is extremely rare. In fracture, moreover, it will be found that the styloid processes of the radius and ulna are displaced with the hand, while in dislocation they occupy their normal relation to the shaft of their respective bones.

Treatment consists, after careful adjustment, in the use of straight dorsal and palmar splints, as recommended for Colles's fracture.

Fracture of the *lower extremity* of the radius—*Colles's fracture*. The lower end of the radius is more often broken than any other part of the skeleton, except the clavicle. Though expanded to articulate with the carpus and carry the hand, this part of the bone is of no great strength for it is formed, except for a compact layer on the surface, entirely of cancellous tissue and this in the old, in whom the fracture is very common, acquires a very open texture in consequence of the partial absorption of its trabeculae. Though occasionally, either alone or in conjunction with fracture of the ulna, the result of direct violence, this injury is in the great majority of cases produced by falls on the hand.

The fracture is generally transverse, but occasionally it is oblique from side to side. It is usually situated at some point within an inch of the articular surface; but the size of the lower fragment is subject to much variety. It may be a mere plate, while sometimes, though rarely, it measures an inch and a half from above downwards and between these extremes all gradations are met with. In some instances displacement is very slight, but most commonly the lower fragment is carried backwards with the carpus, and rotated on its transverse axis, so that its articular surface acquires a certain amount of inclination upwards, instead of looking, as it should, directly forwards; it is also displaced more or less laterally, so that the projection of the styloid process towards the radial side is increased. This complicated displacement produces a very characteristic deformity, best seen when the forearm is raised in the horizontal position to the level of the eye and looked at in profile.

The lower fragment, carpus, and neighbouring part of the hand form a considerable prominence on the dorsal aspect sloping downwards towards the metacarpus, while immediately above is a well marked hollow; on the palmar surface just above the wrist, is a projection formed by the end of the upper fragment, while the level of the wrist itself is a depression corresponding with the dorsal prominence.

thus the shape of the limb is somewhat like that of an inverted spoon. In many cases the hand is inclined towards the radial side, and appears to have dropped away from the styloid process of the ulna, which becomes very prominent. The deformity, as R. W. Smith maintains, depends doubt in some cases on muscular action, the effect of which is clearly seen in the production of the displacement, when, after adjustment, the parts are again left free from restraint. But very often—that is, probably in more than half the cases—is due to the fact that the force applied to the bone has been sufficient not only to fracture it, but to drive the posterior part of the upper fragment into the cancellous tissue of the lower, so that the fracture is impacted.

Other symptoms of the injury are severe pain, and inability on the part of the patient to move the wrist. In some instances, there is mobility of the fragments on each other with crepitus. The opportunity, if occurs, of making a complete examination before swelling has supervened to secure the features of the case, should on account be neglected. Plain as its existence often is, this fracture is sometimes little marked, that it may be, and in fact it rarely is, overlooked. It should be noted that fracture of the lower end of the radius is said by R. W. Smith to occur in adults on the back of the hand, the lower fragment being in that case displaced forwards; but the present writer knows of no specimen which illustrates this condition. In young subjects (under the age of twenty) separation of the epiphysis not rarely takes the place of fracture. In many cases the lower fragment is extensively comminuted, the fracture entering the wrist-joint.

Treatment.—Readjustment is often difficult: sometimes because the fracture is only impacted, in other instances because the lower fragment is small and cannot easily be grasped, or is broken into several displaced pieces; in others, again, from the condition of the tendons. The method most likely to succeed in effecting reduction consists of extension while the hand is supinated and adducted, combined with direct manipulation of the fragments; the direction in which extension is made may be varied according to the case. Though considerable force may be used, it should not be carried to the point of violence, for, after all, extension of the hand does not act very directly on the lower fragment, as no very strong connection exists between these parts, while such

as should be present have been more or less lacerated by the injury. Moderate extension, combined with pressure on the fragments in a direction the reverse of that in which they are locked together, will generally secure the best attainable result. Should reduction not be accomplished on the first trial, the attempt should be repeated a week later, when the fragments may have become somewhat loosened on each other, and when, swelling having subsided, manipulation can be more accurately directed.

Numerous different splints have been recommended for Colles's fracture. Many surgeons prefer the pistol-shaped splint, placed on the dorsal aspect of the forearm and hand, so that the latter is carried towards the ulnar side, and the lower fragment is drawn in the direction opposite to that of its displacement. Often, a short splint is at the same time applied to the palmar surface of the forearm, and is padded so as to take effect on the radius a little above the fracture, and press the upper fragment backwards. Others use the pistol splint on the palmar, and the short splint on the dorsal aspect. Carr's (American) is a palmar, trough-like splint, curved to the shape of the limb, and appended to this a hand-block, over which the palm rests in an easy position. Gordon's splint is in extensive use. The present writer, like many other surgeons, prefers simple straight splints, of the width of the limb, and placed one on the palmar and one on the dorsal aspect of the limb. When adjustment has been secured, and while extension is still kept up, the palmar splint is fixed to the limb by wide pieces of strapping, three for the forearm and one for the metacarpal part of the hand. The splint reaches only to the heads of the metacarpal bones, so that from the first the fingers are left entirely free. The dorsal splint is then applied with wide pieces of plaster, and the two together are surrounded by a bandage. This method efficiently controls muscular action, and, as the dorsal splint can be removed without disturbing the palmar, the fracture can be easily inspected.

Before the splints—whatever form is chosen—are applied to this fracture, great care in modelling the fragments to a perfect adjustment must be used. The deformity which remains after repair is often due, not to recurrence of displacement, but to the fact that it had never been removed. In every case the fracture should be examined, to see that good position is main-

tained, twice or three times in the first fortnight. At the end of a month or five weeks in adults and the old, of three weeks in children, the splints may be discontinued. The forearm should, however, be kept in a sling for a week or ten days longer. In order to prevent stiffness, the fingers should be regularly exercised, and, as soon as the splints are left off, passive movement of the wrist and hand should be employed. The treatment ought not to be regarded as complete till motion has been, as far as possible, restored.

HOWARD MARSH.

RAILWAY INJURIES.—It is a common opinion that railway injuries present peculiar features of general nervous shock, and symptoms of spinal injury distinct from the sequelæ of ordinary accidents.

It is said that the greater severity of such symptoms is accounted for by the suddenness of the accident and the alarming character of the surroundings. It is open to question, however, whether the well-known symptoms that so commonly follow can always be accounted for in this way, for, as a matter of fact, injuries on the platform, and contusions in the street from collisions with railway vans, are nearly always followed by the same symptoms. Again, it is within the writer's knowledge, from experience in the treatment of a large body of men liable to injury from assaults, personal encounters, and street accidents, that symptoms precisely similar to those following railway accidents commonly occur.

As, in railway accidents, it happens that the most trivial injuries are followed by the most formidable array of nerve-symptoms, so it is with the men before mentioned, if injured on duty. The slightest cut or blow on the head, or a kick, is likely to be followed by loss of memory, defective sight, pain in the back, sleeplessness, and all the usual symptoms of nerve-shock. There is a condition common to both classes of injury, which must not be lost sight of by the practitioner. A person hurt on the railway knows that in nearly every case he is entitled to compensation, and the official, injured on duty, knows that he is entitled to a pension for life, if it is proved that he is incapacitated from the further performance of his duty thereby. On the other hand, the ordinary accidents of every-day life, such as falls downstairs, carriage accidents, and falls in the hunting-field, are not usually followed by such an array of nervous symptoms.

This assertion brings one face to face with very delicate questions—viz. how far

are those symptoms dependent on the injury, and how far are they dependent on the probability of obtaining pecuniary compensation for the injury? Then there is the further question. How far are the symptoms compatible with the reasonable anxiety and worry which are imposed by the prospect of litigation, and, on the other hand, how far are such symptoms purposely exaggerated or assumed? These are questions which must always exercise the mind of the practitioner who is called upon to attend such cases.

Railway injuries may be divided roughly into four classes, viz.: 1. Contusions and shocks, the result of slight collisions. 2. Fractures, dislocations, and concussions, caused by severe collisions and wrecks of trains. 3. Accidents on the line, including crushes by buffer accidents and limbs cut off by passing trains. 4. Platform accidents, caused by falls while getting in and out of trains.

Accidents belonging to the first class enormously preponderate, and as they are followed by every variety and degree of nervous shock, including the so-called railway spine, they demand the special attention of the surgeon.

Accidents of the second class present no special features distinguishing them from other injuries, and it is worthy of note that, after severe fractures and dislocations, the nervous symptoms are commonly less severe and less prolonged than after apparently trivial injuries.

Accidents of the third class generally occur to railway servants, and are often fatal. In shunting accidents, the abdominal or pelvic viscera are the seats of injury, and death may be occasioned by internal hæmorrhage, or by shock alone. In these cases, it often happens that the most extensive and severe internal lacerations may be present, without any external lesion or even a bruise. The injuries inflicted on limbs by carriage wheels are necessarily very severe, often resulting in immediate division of the part, or if not, so crushing the bones and soft parts as to require, in nearly every case, primary amputation. The distinctive character of these cases is that they are commonly fatal, in spite of the fact that the injured person is immediately carried to the nearest hospital, or surgical aid is obtained as quickly as possible. The usual explanation of the fatal issue is that it is caused by shock; but why a cleanly divided leg or forearm should cause fatal shock is at first sight difficult to understand. The explanation is that hæmorrhage in such cases is

very severe. The sharp edge of the wheels and of the rail act like scissors, and often divide a limb, or even the trunk, as if cut by a knife.

It is only quite recently that railway companies have seen the importance of providing immediate surgical aid, and the fatality of such accidents in the past has no doubt been due chiefly to hæmorrhage, and not, as was usually supposed, to shock. This fact is now so well recognised, that two of the largest railway companies in England have provided Esmarch elastic bandages, to be kept at every station, accompanied by printed directions for their use; and have also made arrangements for periodical instruction to be given to the officials and porters. (The instructions will be referred to under the head of *treatment*.) Again, ambulance classes are being held at most of the large railway termini, and it is to be hoped that a more general knowledge of how to give first aid to the injured will materially lessen the fatality of such accidents.

The fourth class, or platform accidents, may be sub-divided into two sections—1. Those caused by falling between the train and the platform, which are nearly always fatal, from the body being dragged down between the footboard of the carriage and the edge of the platform, thereby tearing off limbs, fracturing the pelvis, and causing terrible injuries. 2. Falls on the platforms, which are very common and entail much litigation. These injuries are seldom serious, but there is the disturbing element of litigation nearly always present, and there is generally a question as to the liability of the company. Moreover, it is a curious fact that some of the most aggravated cases of nervous disturbance and heavy claims for damages have arisen from trivial injuries of this class.

NERVOUS SHOCK.—This condition may be described as a functional disturbance of the sympathetic nervous system, directly affecting the vital functions, and also indirectly disturbing the functions governed by the cerebro-spinal nervous system. It is the peculiarity of railway accidents that nervous shock follows every conceivable variety of injury. It has hardly ever been the experience of the writer to see a crushed finger, a cut head, or a broken nose, or any other trivial accident occurring on a railway, which has not been followed by more or less nervous shock.

In considering the symptoms, it will be convenient to classify them as affecting

the different functions of the body and the organs of special sense.

Circulation.—The heart is primarily affected; the action is weakened and the beats are quickened and irregular. The pulse is rapid and weak in unison, and the surface of the body pallid and cold. The temperature often sinks one or two degrees below normal, and the body is bathed in a cold sweat. This condition may pass off in a few hours, or it may continue in a modified form for weeks or months.

Digestion.—The stomach is immediately affected by the nervous disturbance, as indicated by vomiting, foul tongue, indigestion and all its concomitant symptoms, loss of appetite, constipation, flatulence, and palpitation of the heart. Then follow loss of flesh, hepatic disturbance, mal-assimilation of food and gouty disorders, and even albumen in the urine may occur.

Sleeplessness.—This condition is always associated with nervous shock. Sleep, of course, is not totally absent, but it occurs in short snatches and is disturbed by dreams and visions, and there is no sense of refreshment or rest on awakening.

Sight.—This is usually impaired; dimness of vision and specks floating before the eyes are complained of. The pupils of the eyes appear abnormally dilated, and it not infrequently happens that the power of continuing the effort of reading is found to be notably diminished. This may be, and often is, the result of impairment of the function of accommodation by which the eyes are adjusted for near objects, or it may be a sort of inco-ordination arising from the nervous shock, and likely to pass away as the shock is recovered from. See VISION, Disorders of, from injuries of the head and spine.

Memory.—It is difficult to estimate how far the memory may be impaired. Patients usually complain that their memory is entirely gone, but at the same time they will relate, in minute detail, every incident connected with the accident, and give a long history of their symptoms. The truth is, the memory is not impaired, but the mind is alienated from the usual course of thought, and centred on the incidents of the accident. Thus, there is a difficulty in conversing on ordinary subjects, and a slowness in finding words to express the thoughts.

Moral Sense.—Nothing appears more demoralising than a railway accident. It is a common statement for a patient to make, that there has been no sleep for a month, or that not a morsel of food has been taken, and it is often painful to see the open at-

tempts at imposition. This happens constantly in persons who have been really injured, and is different from the deliberate and well-planned attempts to deceive which are characteristic of the malingerer.

Sensation and Motion.—These functions are frequently impaired. Anæsthesia is often found in men as well as in women, without any other symptom of hysteria. It frequently attacks the whole of one side of the body, and may occur with or without loss of motor power. The pulse on the affected side is small, the temperature is subnormal, and the skin pale. An arm, a leg, or even the course of a single nerve may be affected. Paralysis, again, is a very common result. It may take the form of paraplegia or hemiplegia, and is generally associated with anæsthesia. In these cases, the electric contractility of the muscles is usually unimpaired, but the sensibility of the muscles is more or less lost. Grave errors are of constant occurrence in the diagnosis of these affections, and after railway injuries there is a general tendency to attribute all such symptoms to spinal lesions, whereas, as a matter of fact, it is a very rare thing to find any spinal lesion following directly on railway injuries. The symptoms of hyperæsthesia and anæsthesia and paralysis, which so often follow such injuries, are in most cases purely functional, and correspond, in all their phenomena, to the symptoms which occur in ordinary hysteria. Other symptoms indicating some loss of the inhibitory power of the cerebrum are generally found—viz. the tremulous motion of the tongue and the shaking of the hands, as well as the tendency to cry when spoken to. Exaggeration of the reflexes is common, and sometimes even ankle-clonus is found.

Hearing.—Deafness is sometimes found, but it is not common. Persons often complain of noises in the head and inability to bear the slightest noise without starting.

Taste and smell are rarely affected, except in cases of hysteria.

Nervous shock may be the result of fright or of a very slight injury, and it is often a question whether it is not more the result of the events following than of the accident itself. Often, the sequence of events after a railway accident is as follows. The frightened or injured person is immediately dosed with brandy. He is naturally nervous and excited, and on arriving at his destination the doctor is sent for, who does not always reassure his patient. Then follows a sleepless night, with dreams and visions, and thoughts of

paralysis and spinal injury. Rest, narcotics, and stimulants are prescribed, with the usual results of dyspepsia and headaches. The patient becomes really ill and nervous, as well as apprehensive. At this period, a plucky resolve to throw physic away and stick to work would soon re-establish the usual health, but unfortunately there is, generally, passive resignation, and no effort of any sort is made to resume work. Should there be an attempt it is not persevered in, and the patient, without actively intending to impose upon himself and others, will soon work himself up into a state of nervous apprehension, which rapidly develops all the symptoms of severe nervous shock. It must also be remembered that a person may actively encourage emotional disturbance, by which a similar result may be produced. This condition may be justly said to be a borderland which approaches malingering as nearly as can be.

On the other hand, no doubt many cases occur where a severe shake or concussion does produce general nervous shock, the effects of which it is very difficult to shake off, and which renders the patient absolutely unable to follow his usual avocations. Again, severe shock may accompany traumatic lesions of the limbs or organic injuries to the viscera or nerve-centres; but, in the majority of cases where nervous shock follows a railway accident, it is a moral disease and is not directly due to any physical injury.

In ordinary cases, shock to the nervous system is completely recovered from after a variable period, but elderly persons are sometimes permanently affected. The early symptoms may not be severe; in fact, the emotional condition may be absent, and there may be no special symptom beyond a general sore feeling in the back or legs. Soon the usual cheerfulness is lost, the gait becomes feeble, the circulation weak, and the person gets thin and pallid. There may be no headache, nor loss of sleep, nor any particular pain, yet complaint is made of feeling ten years older, and friends and acquaintances corroborate the statement, judging from appearances. In such cases, there is nothing of the nature of spinal disease to be apprehended in the future; but it may be taken as a general rule that the person will never be as well as before the accident.

CONCUSSION OF THE SPINE.—This is a term difficult to define, for, as the phrase is usually employed, it includes several distinct conditions:—1. A jar or shake to the spinal cord, causing pain and disturbed innervation without any symptom of special lesion.

2. A condition depending on pressure, either of extravasated blood or by exudation of serum. 3. Alterations in the structure of the cord itself, the result of chronic inflammatory changes either in the substance or in the coverings of the cord. The term 'railway spine' is often applied indiscriminately to any of these conditions. These may be the result either of direct or indirect violence. The primary symptoms will, of course, vary according to the severity and position of the injury. In the upper cervical region, grave danger may occur to life from implication of the large nerve-trunks, which take their origin from the medulla oblongata. If the vagus nerve be affected, the symptoms of dyspnoea will be urgent; if the phrenic, a feeling of constriction of the chest, caused by paralysis of the diaphragm will be felt. A blow on the lower part of the cervical spine has been known to induce paralysis of both arms, without any paralysis of the trunk or legs; sometimes there is loss of sensation, in other cases there is hyperæsthesia, but in this respect there is every variety and combination of nerve-disturbance.

A blow on the dorsal or lumbar region may cause complete loss of voluntary power in the lower limbs, with or without loss of sensation. One leg is usually more affected than the other. The patellar reflex also is generally much increased. There is often complete loss of power over the bladder, accompanied by incontinence; less frequently there will be retention. The usual symptoms of nervous shock will be present, the most prominent being pain in the head, furred tongue, constipation, pain in the back, and intense neuralgic pain in the affected limbs. A pricking sensation is also often complained of, and there is great skin sensibility over the lumbar and sacral regions. There is pain on pressure—generally referred to the lumbar region in the middle line, and radiating to the sides. There is difficulty in turning over in bed. If walking be possible it appears difficult; the legs are spread open as if to make a wider base for support, and the position of the body is fixed and constrained; there is no power to stoop to pick up anything; the appearance is as if the sacro-iliac joint were injured.

A marked peculiarity in cases of concussion is the frequent coincidence of nervous disturbance, affecting the part supplied by the spinal nerves which emerge opposite to the part struck. On the hypothesis of concussion of the substance of the cord this is difficult to understand. One would expect the nervous disturb-

ance to be wider in its radius; and when it is considered how thoroughly the spinal cord is protected from external injury, both by its solid case and elastic surroundings, also how completely it is protected from jar through being suspended in a double tube—viz. the spinal canal on the outside, and the fibrous sheath (with an interspace of fluid) on the inside,—it seems reasonable to suppose that the nerves which emerge from the injured spot are alone affected. The cord being somewhat movable, it is easy to understand how a sudden blow may cause a stretching or strain of the nerves as they pass through the intervertebral foramina, or the nerves may be pressed upon by an effusion of serum or blood outside the sheath of the cord. No doubt this often happens; and, even when symptoms of injury to the cord may co-exist, it is more than probable that they may be caused by irritation reflected from the injured nerves.

For a description of injuries to the muscles and ligaments of the back, see BACK AND SPINE, Injuries of the.

REMOTE INJURIES.—It is a commonly stated opinion that railway shock is peculiarly liable to be followed by organic disease of the spinal cord. The experience of the writer, however, does not support this view, for during the last six years, out of more than 500 cases examined, where claims have been made for personal injury, in half-a-dozen cases only were undoubted symptoms of organic disease found. Two of these were cases of tabes dorsalis, and a third a case of cerebral hemiplegia. In another, paralysis from disease of the spinal cord was present, but in this case the symptoms had commenced before the accident. No doubt, after spinal concussion, slow inflammatory changes occasionally occur in the cord or in its membranes, and may result in degeneration of nerve-tissue. Two forms of degeneration have been described: the one chronic meningitis with myelitis, the characteristic signs of which are a localised pain in the spine, greatly increased by movement, rigidity of the body or of the limbs, with spasmodic contraction of muscles and great muscular rigidity. The patient resents the slightest displacement of the body. These symptoms are generally accompanied, more or less, by cerebral symptoms—viz. headache, loss of memory, intolerance of light, suffusion of the eyes, noises in the head, &c. There is no paralysis of the sphincters, but often some loss of motor power affecting one or more of the limbs. There is exaggeration

of reflexes, also skin hyperæsthesia extending along the course of the nerves, and sensations of pins and needles in the limbs. There is a peculiar, unsteady, rolling gait; the legs are placed far apart, the heels drag, and the body is kept rigid either in the erect or bent posture. The other form of degeneration is sclerosis. This condition may no doubt follow traumatic injuries of the cord, but is more likely to be the result of mental shock or prolonged hysteria. There are no definite symptoms except a gradually increasing paresis of the lower limbs, extending ultimately to the upper limbs. There is no loss of ordinary sensibility; the muscles shake and quiver when called into action, ankle-clonus is distinct, and the reflexes are often exaggerated; there is no wasting of the muscles, nor any loss of electrical excitability.

Tabs dorsalis may, possibly, be a rare result of railway injury. In these cases sclerosis of the posterior columns is found, but it is more probably the result of indirect causes than of actual injury to the cord. Of the two cases which occurred in the writer's experience, in one there was a history of symptoms before the accident, and in the other the man was of an intensely neurotic temperament, and, besides the railway shock, had recently been subject to domestic bereavement, and had great business worry. There is another condition described which is known as 'spinal anæmia,' but it is questionable whether this is a pathological condition. It is generally accompanied by hysteria. The symptoms are as follows:—There is intense hyperæsthesia, greatly increased by pressure and by the application of a hot sponge; the tenderness is usually diffused more or less over the back: it has no tendency to follow the course of the nerves. In the more severe cases, there is often loss of motion in the lower extremities: the legs and feet are cold, and the reflexes are absent. In this case, again, it will be found that the sphincters are not paralysed, and that the general health is often good.

Hysteria is a common sequence of nerve-shock, especially with women. The patient becomes emotional; she bursts into tears, or is quick-tempered and violent; she dwells on her symptoms, exaggerates all her injuries, is untruthful, and her moral nature appears perverted. She may simulate disease consciously or unconsciously, and practise all sorts of tricks in order to deceive the persons around her. Hysterical paralysis is very common after railway injuries. It usually takes the form of para-

plegia. Tonic spasm of the limbs is also frequent. Hyperæsthesia, anæsthesia, convulsions, and mania are all common in these cases of hysteria.

METHOD OF EXAMINATION.—A practitioner, who is called on to report on a railway accident, cannot be too careful in keeping an accurate record of the case. The notes should be taken as follows:—State the date and place of examination; name, sex, age, occupation; married or unmarried; in the case of women, number of children; date and place of accident, and also the patient's description of the accident and events immediately following; when seen by a doctor, and by whom; patient's history of symptoms to date; patient's description of present condition. In examining the patient, avoid putting leading questions as far as possible. Make a note of each organ examined, and describe any local injuries found.

Where injury to the spine is supposed to exist, examine by percussion; examine surface sensibility by hot sponge, by touch with the finger, or with a feather.

Where paralysis is alleged, measure the limbs most carefully and compare them with each other; note the strength of the muscles by the grasp of the hand or power of locomotion; examine the patellar reflex, and also the power of contraction of the muscles generally, and whether ankle-clonus is present. The electrical irritability of the muscles may be tested, but there is a great deal of confusion existing regarding the utility of the electrical phenomena. This is due, not so much to the difficulty of interpreting facts, as to the general absence of technical knowledge necessary to elicit them with accuracy and precision.

The eyes should always be examined, and the condition of the pupils noted. An ophthalmoscopic examination is also desirable, and in some cases essential, as the existence of lesions of the retina may be confirmatory of cerebral or spinal symptoms.

The urine should always be examined for albumen and sugar, and the specific gravity should be taken, as well as the reaction with litmus paper. If possible, the medical history of the case should be taken down as related by the patient's medical attendant, and the treatment, past and present, noted. It is also desirable that a consultation should be held apart from the patient, in which the medical men in attendance on the patient should be invited to take part. This procedure is not always followed, and sometimes may not

be considered necessary or expedient. The diagnosis of the injury should be agreed upon as far as possible, and a note should be made whether opinions coincide as to the diagnosis and prognosis; especial note should be made of the period that will be probably required for partial or complete recovery. The amount of compensation should not be discussed; it is, however, quite within the province of the medical men to agree upon a time, during which the patient is likely to be incapacitated, as a basis whereon the railway company may estimate the amount of compensation that should be awarded.

All original notes of the examination should be carefully preserved, and they should be made at the time of, or soon after, the examination.

COMPENSATION.—Occasionally, both the claimant and the railway company agree to have the amount fixed by the medical men. It is not a task that should be lightly undertaken by them, and it should never be considered a part of their duty. In dealing with this subject there are three points to be considered:—1. How long has the claimant been incapacitated from business? What has been his loss thereby, and how much expense has he legitimately incurred? 2. How long is he likely to be incapacitated and what loss and expense is he likely to incur in the future as the direct consequence of his injuries? 3. What is a fair sum to fix as a solatium? In other words, how much should be paid for the pain and suffering he has had to endure?

Considerable diversity of opinion may naturally be expected on this latter point, and, at first sight, it would seem only fair that the position in life of the claimant should make no difference in assessing the solatium. Thus, if a labouring man with a broken leg should be paid £100 for his pain and suffering, a professional man earning £1,000 a year should only be entitled to a similar amount. Juries, however, do not usually take this view, and the heavier the pecuniary loss, so much the more do they give as solatium. After all, this is not unreasonable, for £100 to a labouring man would appear a good sum, whereas to the professional man it would be a very poor recompense for the suffering he had undergone. It is the practice to take into consideration the comparative value of money to the injured persons. This, however, should be done only within narrow limits. It would be impracticable as applied to a peer with £50,000 a year,

and would be most unjust to the railway companies, though no doubt £5,000 would not appear of greater money value to him than £500 to the professional man, or £100 to the workman.

Arrangements as to compensation, made between the company's medical man and a plaintiff, are scarcely ever proper, and never prudent. To say nothing of the fact that the bargain for terms of settlement is not the business of a medical man, the parties are not upon equal terms, their means of knowledge are essentially different. The more delicately and kindly the medical man has discharged his duty in watching the case on behalf of the company, the more will a kind of confidence on the part of a sufferer have sprung up, which tends to place him at an additional disadvantage. So strong is the feeling against such arrangements, that they can rarely be maintained. There is no legal difficulty in their way; the doctor is not the doctor of the patient, and there is no such 'confidential relation' as renders them theoretically incapable of enforcement. But they are open to so much of well-grounded suspicion that juries will rarely believe they are honest, and judges are prone to take the same view, so that they have a very slender chance of success; whilst the mere fact of having attempted to make them is felt to be discreditable, and to lower the position and reputation of the medical man to whom it is brought home. As before mentioned, cases may sometimes occur, in which the medical man employed by the company and the medical man employed by the plaintiff may fairly and properly come to arrangements for settlement of claims for personal injury. But, even here, there is frequently room for suspicion and unfavourable comment. When, as has sometimes happened, it has been part of such an arrangement that the company should pay the bill of the medical man who has acted for the patient, the bargain, however honest, is likely to be treated by juries as fraudulent, if afterwards assailed by the patient, and no prudent or experienced practitioner ought to place himself in a position from which he can scarcely escape without discredit.

PRIVILEGED COMMUNICATIONS.—Communications between solicitor and client are privileged from discovery, so also are all documents prepared for the *bonâ-fide* purpose of being laid before the solicitor of the patient in order that he may advise his client thereupon, whether prepared at his instance or not. Reports therefore made

really, and not merely colourably, for the purpose of being laid before the solicitor of a company to assist him in giving his advice to the company or its directors or officers, are privileged from production to a plaintiff. Not so, however, if prepared for the use primarily of the directors, so that, as a general rule, reports or letters addressed to the directors, secretary, manager, or other officer of a company may be inspected under a judge's order.

Notes of verbal reports fall under the same rule. If intended for the use of the solicitor to enable him to advise his clients, they are protected. If for the use of some officer of the company or the directors, they are liable to inspection.

PROFESSIONAL ETHICS.—In arranging examinations and consultations, there are many points to be observed. A medical man, acting on behalf of a railway company, has no right to examine an injured person except with the consent of the patient, his doctor, or his solicitor. If such consent be not given, and if an action is pending, there is no power of compelling a medical examination of a plaintiff except in the manner provided for by 31 & 32 Vict. c. 119, sec. 26, which is, that the judge may order an examination, for the benefit of the tribunal, by a medical man named by him who is not a witness. This is rarely acted upon, consequently, an examination being a matter of arrangement merely, the plaintiff can impose any conditions he chooses, and the other side must submit; thus, the solicitor for the plaintiff may insist on being present. In such case, of course, the solicitor for the other side has a right to be present also.

In consultations between the medical officer of the railway and the plaintiff's doctor, the former usually fixes the appointment, for the reason that he often has a long distance to travel, and is generally a consultant; but, of course, the plaintiff and his doctor and solicitor have a right to fix the time and place for the examination. If several consultants be engaged, it is usual for the consulting officer of the company and the ordinary medical attendant of the patient to arrange the appointments. Sometimes the fixing is left to the solicitors, but it is not a good plan, as they do not know how best to study the convenience of the consultants.

A railway surgeon should never consent to examine a plaintiff in the presence of his solicitor alone. If the plaintiff's doctor cannot be present, then the railway company's solicitor should attend as well,

but it is never desirable that solicitors should be present at a purely medical or surgical examination. Again, a railway surgeon should never visit a plaintiff alone, if it can be avoided. In the case of *Casson v. Great Western Railway Company*, tried at Birmingham, the plaintiff swore to a conversation between himself and the doctor, not a word of which had ever taken place. Luckily, an inspector was present, who was able to prove that the conversation, which was narrated, had taken place between himself and the plaintiff on a previous visit. Leading questions should not be put, nor is it wise to make any remarks bearing on the case, in the presence of the plaintiff. It is no part of the duty of a railway surgeon to interfere with the treatment, though, as a matter of fact, suggestions are often asked for and adopted by the plaintiff's doctor. Sometimes, an injury is discovered by the railway surgeon which had not previously been diagnosed. Opinions may vary as to his duty in such a case. The writer has no hesitation in saying that it would be incompatible with a high standard of duty and professional honesty to conceal such a discovery. Although he is surrounded by pitfalls on every side, and sees tricks and deceit constantly practised, absolute professional honesty and candour should be his guide in every case. It must be remembered that medical men attending cases of railway injury have no right to increase their fees. The scale should be such as would be charged to persons in the same rank of life, suffering from ordinary illness. With regard to attendance in court and journeys on behalf of railway companies, special arrangements should be made beforehand.

MEDICAL EVIDENCE.—With regard to medical evidence in cases of railway injury, there is much that is unsatisfactory. There are, unfortunately, medical men who encourage fraudulent claims, by acting in concert with speculative solicitors. In case of the claim being lost they agree to waive payment, but, if compensation is obtained, they get a good share of the plunder. Again, some men ignorantly encourage fraud by recklessly asserting that every slight case of injury is likely to be followed by disease of the spinal cord. It is also very common for medical men to allow their sympathy for an injured person to influence their judgment, beyond all bounds of fairness and common sense. On the other hand, it is alleged that railway surgeons commonly ignore all injuries, and it is a usual custom in courts of law to attempt

to discredit their honesty. Whether this imputation be deserved or not, it has led to a most unfortunate custom—that the very suggestion of possible fraud, even in the most flagrant case, is sure to bring down on the surgeon a vigorous attack from the plaintiff's counsel, and a cross-examination intended to suggest want of honesty and indifference to anything except the interest of the railway company. The eloquence on this point is usually so effective with the jury, that the counsel for the defence is unwilling to allow any imputation of fraud to be made, even if there is clear evidence of it.

It must be conceded that it is the duty of the railway surgeon to keep an unbiassed mind. He sees so many cases of attempted and successful fraud, that there certainly is a risk of his mind being soured and his judgment perverted. In every case, he should be able to give his reasons for statements and opinions, and he must take care not to allow any amount of exaggeration or fraud to turn his mind from the recognition of injuries that do exist. There should be no suppression of opinion that might be unfavourable to the company. It has sometimes happened that opinions expressed by the medical witnesses for the plaintiff have appeared to the counsel for the defence less prejudicial to his case than the opinions held by his own professional witnesses, and in defending the action he has wished to adopt the theory of the other side; but the zeal of the advocate should never extend to the medical witness. It would be a gross impropriety for him to suppress or modify his opinions at command of counsel; the only alternative, for a counsel who wishes to adopt the opinions of the other side, should be not to call his medical witnesses.

The witness should remember that technical terms are to be avoided as far as possible, and that his opinions should be expressed in such language as to be intelligible to the judge and jury.

Again, the medical witness should know that all original reports and notes are liable to be called for, and, if so, must be produced. The witness should never lose his temper, and all questions should be answered respectfully and to the point. Where it is impossible to answer a question without an explanation, it is better to appeal to the judge for permission to make it. Counsel are very apt to insist on 'yes' or 'no' for an answer in cross-examination, but, of course, are bound to allow an explanation if the judge permit it.

Diagnosis.—The difficulties of diagnosis in railway injuries are well known, and are being continually illustrated in the law courts. This is not to be wondered at, as we may have, mixed up in one subject, the symptoms of fright, nervous shock, injuries to muscles and ligaments, hysteria, spinal and brain concussion, organic injury to brain or spine, and, added to these, symptoms either imagined or invented. The first point, of course, in diagnosis, is to differentiate symptoms of real disease or injury from those imagined or invented. That malingering is common cannot be denied, but the medical man is never justified in concluding that symptoms are assumed (however inconsequential they may appear), until he has satisfied himself by the most careful tests that they cannot be produced by nervousness or hysteria. The variety of cases in which such tests require to be applied, precludes the possibility of giving any general rule for testing the genuineness of symptoms. The surgeon must rely on his own judgment and sagacity in each individual case. Mr. Erichsen writes: 'When symptoms are invented or wilfully exaggerated in order to mislead, the fraud may usually be detected, by a surgeon accustomed to these investigations, by finding that the symptoms do not bear a due proportion to one another, that one is brought into greater prominence than the rest, and that the patient contrives to direct attention to and lay emphatic stress on it. There is, in fact, an absence of that harmony of symptoms which characterises all true and real diseases.'

Notwithstanding the extreme difficulty in diagnosing the effects of railway accidents, opinions are given and sworn to in these cases, with a recklessness which would be deemed most culpable in ordinary illness. One reason is that the directors of the railway companies require from their surgeons a definite opinion on the case at an early period—first, as to the nature and extent of the injury, and whether it is likely to be permanent; secondly, how long the effects will last or incapacitate the person from his usual employment. These opinions have to be formed, generally, after a single visit. On the other hand, the practitioner in attendance is equally pressed by the injured man's friends or solicitor for his opinion, in order to make a statement of claim for compensation; and thus it is that, on the one side, insufficient opportunity for observation, and, on the other side, inexperience or undue bias in the interpretation of the symptoms which so commonly follow

railway accidents, lead to such divergences of opinion, and such pitiable exhibitions in the witness-box, as to be a byword of reproach to the medical profession. In injuries where there are objective symptoms, the same rules of diagnosis will apply as to ordinary accidents; but often, when the railway surgeon examines a case, all objective symptoms will have disappeared, and yet allegations may be made of grave injury remaining.

It cannot be doubted that the diagnosis between malingering and hysteria is most difficult. It has happened, again and again, that symptoms which have been pronounced hysterical by the most competent physicians have disappeared directly after the trial; and in one case lately tried, where large compensation was obtained, and where the doctors on both sides agreed that the case was one of aggravated hysteria, the woman took a public-house directly after the accident, and boasted to her customers how she had 'done' the doctors.

After falls on the platform, a claim is often made for permanent injury to the hip-joint. No doubt, a fall on the hip may either bruise the joint, or may cause some inflammatory exudation around the sciatic nerve. Lameness and pain are complained of, and large claims for compensation are made. The difficulties in the diagnosis are as follows:—First, whether the patient is really suffering; secondly, whether, if suffering be present, it is due to the injury or to ordinary sciatica or rheumatism of the joint.

Ruptures are often discovered after railway accidents, and no doubt a sudden jerk may produce a hernia; but if coming down for the first time through violence, great pain would immediately be felt, whereas, in the great majority of the cases complained of, it will be found that the rupture was discovered only some weeks or months after the accident, and usually after a claim for compensation had been made. It is a very common method of making a fraudulent claim. In some cases, no doubt, fraud is not intended. The plaintiff is thoroughly overhauled for the purpose of making a statement of claim, and the rupture is discovered for the first time. It is necessary in such cases to make close inquiry into the history of the swelling, whether a truss has ever been worn, and whether the patient has been ever examined for a club or for life assurance. It is sometimes impossible to say how long a hernia has existed. The abdominal rings may have been weak and

bulging for years, and the slightest exertion may bring on the hernia, without causing pain or inflammation; but a hernia, coming down through a strong abdominal ring on account of violence, would be accompanied by sudden pain, and probably sickness and shock.

It is possible that a hydrocele may be caused by a blow on the testicle. In a recent case, such an injury was alleged to have been caused by a railway accident. A month after the accident one testicle was enlarged, and very hard and irregular. There was a good deal of fluid in the tunica vaginalis, but the tissues were much thickened by chronic induration, and not thin and distended as in a recent case of inflammatory exudation. Again, the surgeon who examined the plaintiff directly after the accident found the testicle in exactly the same condition as at the later examination. This was reported as a fraudulent claim, and compensation was refused.

Where injury to the nervous centres is suspected, the following points in diagnosis must be made out:—1. Whether the symptoms are real. 2. Whether the symptoms are due to a general shock to the nervous system. 3. Whether to concussion of the brain or spinal cord. 4. Whether to organic injury or disease affecting the brain or spinal cord or nerve-trunks. 5. Whether to injury to the muscles or ligamentous tissues of the back. 6. Whether to rheumatism. 7. Whether to hysteria.

Now, considering that the symptoms may be purely subjective, and that nearly all the above conditions may co-exist, it will be understood how difficult the question of diagnosis must be in certain cases. The history of each particular case must be minutely investigated, and a careful comparison of the subjective with the objective symptoms must be made. Again, where malingering is suspected, the relative compatibility of the symptoms must be examined. It must also be remembered that there are different degrees of malingering:—1. There may be the actual assumption of symptoms which have no existence. 2. The reference of old diseases or symptoms to a recent accident. 3. The wilful exaggeration of injuries which really exist.

In general shock to the system, the diagnostic symptoms are mostly subjective—viz. sleeplessness, headache, loss of memory, defective eyesight, constipation, pain in back; the objective symptoms being disturbance of the circulation, weak or intermittent pulse, foul tongue, and exaggeration of the reflexes.

When there has been concussion of the spinal cord, there is pain in the back, generally most severe in the lumbar region; pain on pressure over the spines of the vertebrae, varying in extent; hyperæsthesia of skin; irritability of the bladder; diarrhoea or constipation; great pain in turning over in bed, or, if able to get up, inability to stand upright or straighten the back; a stiff and constrained position in walking, with the legs spread open as if unable to balance the body; radiating pains of a neuralgic character down the legs, and feelings of pins and needles.

In brain-concussion there is the history of a blow on the head, loss of consciousness at time of accident, subsequent pain in head and confusion of ideas, suffusion of eyes, intolerance of light, feeble pulse, accompanied more or less by symptoms of general shock.

Where paralysis is present it may be functional (including hysterical paralysis), or it may depend on organic injury to the brain or spinal cord or peripheral nerves. In functional paralysis the muscles retain their nutrition, or, if there be wasting, this is of the character of general emaciation from simple disuse, and is not an atrophy of particular groups of muscles. As a general rule the electrical reactions are normal, but after very long disuse there may be sometimes, at first, a slight loss of irritability to induced currents. After a very few applications, however, this passes off. It is to be noticed that the lowered irritability obtains equally as regards not only the induced, but the galvanic, current also.

In paralysis from lesions of the brain, there is ordinarily nothing abnormal to be noted in the electrical reactions of the muscles of the affected limb, and this applies also to a lesion limited to the lateral or posterior columns of the spinal cord. But, if the anterior horns of grey matter in the cord be affected, there are—1. Loss of power in certain muscles of the limb supplied by nerves issuing from the affected part of the anterior horns. 2. The tendon reflex in the affected muscles is absent. 3. The paralysed muscles tend to atrophy. 4. Examined electrically, it is found that the reaction to induced currents is materially lessened or entirely absent, and this whether the rheophore be applied either to the muscles or the nerves supplying them. If, however, the rheophore conveying a galvanic (constant) current be applied to the muscle, and the current slowly made and broken, there will be contraction—

strongest when the positive pole is applied. If the galvanic current be applied to the nerve only, there is no reaction.

Similar phenomena result when, instead of disease in the anterior horn of grey matter, the lesion is situated in the trunk of a motor nerve. They are absolutely indicative of organic lesion of a certain part of the spinal cord or of the trunk of a nerve. A destructive lesion of the spinal cord, high up (say in mid-dorsal region), will cause complete paralysis of the lower extremities and viscera, and yet the electrical reaction of the paralysed limbs will be normal, because the anterior horns of grey matter, at the point of origin of the motor roots of nerves going to the limbs, are unaffected. The paralysis here depends not upon lesion of the anterior horn of grey matter, or of the trunk of nerve, but upon the interruption to the descent of voluntary impulses from the intracranial centres along the antero-lateral columns of the cord. The tendon reflexes in this condition are exaggerated. They are also in excess as a result of secondary degeneration from disease of the motor area of the cerebral cortex. They are usually also heightened in functional paralysis. It may be said, generally, that the conditions of the muscles in functional paralysis, as regards electrical reaction, nutrition, and tendon reflex, resemble those of limbs paralysed as a result of cerebral and not spinal lesion. The diagnosis between functional paralysis and paralysis from an intracranial lesion requires the consideration of a large number of possibly attendant circumstances, the discussion of which is impracticable in an article of this scope. Reference must be made to special works upon disease of the nervous system.

The use of electricity, as a diagnostic agent in investigating injuries after railway accident, may be summed up shortly as follows. If, in a given case of asserted paralysis, the electrical reactions are found to be universally normal, it may be concluded that the injury is not due to any organic disease of the muscles, the nerves, or the anterior cornua of the cord. It does not, however, exclude lesions of other portions of the cord, such as lateral sclerosis, locomotor ataxy, affections of the brain, such as cerebral hemiplegia, or functional disorders such as hysteria. In these the electrical reactions are practically normal, and the diagnosis must be determined by other concomitant symptoms. If, on the other hand, positive evidence of abnormal electrical reactions can be obtained, it is a

certain proof of organic tissue-change in either nerve or muscle. These abnormal changes may be in nerve alone, in muscle alone, or in both together. They may be distributed in a variety of ways, a knowledge of which, combined with the other circumstances of the case, generally enables the inquirer to diagnose the seat of lesion—that is, whether it originates in the nerve, the muscle, or the cord.

As a matter of fact, organic disease of the nervous centres is of very rare occurrence after simple collision, and even after direct traumatic injury to the spine it is not common.

Where injury to sight is alleged, it will of course be a question for diagnosis whether the eye has been directly injured. Such cases would not be likely to differ from wounds or contusions arising in any other manner, but claims for remote or indirect injury are frequently made, and no doubt are, in a certain proportion of cases, well founded. A person, who is confined to bed or to a sofa by the effects of a railway collision, would often be desirous to while away the tedium of such confinement by reading, and it is often found that the power of continuing the reading effort is diminished. So long as the distant vision remains of normal acuteness, or can be brought up to normal acuteness by a lens, the mere failure of reading power need occasion little or no anxiety. It is a symptom of nervous shock which will disappear with restoration of the general health, or which, at most, will require an earlier employment of spectacles than might otherwise have been necessary. Sometimes, however, the acuteness of distant vision suffers, and then, even if the diminution should at first be but trifling, the case assumes a serious aspect. Injuries to the nervous centres may affect the optic nerve and retina in two ways: by the production of neuritis, probably leading to eventual atrophy and blindness, or by an atrophy without antecedent neuritis, a so-called 'simple' or 'sclerosal' atrophy, which, although producing great impairment of sight, sometimes stops short of complete blindness, and which may probably be attributed to injury of the nerve-centres which govern the nutrition of the optic nerve.

In every case in which impairment of vision, as distinguished from diminution of endurance, is complained of, the eye should be subjected to early and complete examination with the ophthalmoscope, by which, in the earlier stages of neuritis, some

blurring of the disc and some vascularity of the nerve-tissue will be detected; while, in the instances of simple atrophy, the nature of the change must before long be apparent. At the same time, the actual state of the visual function, as regards acuteness, extent of field, colour sense, and accommodation, should be investigated as carefully as circumstances will permit, and with reference not only to prognosis but also to treatment. The surgeon will frequently have to deal with cases in which the truth is more or less obscured by nervous excitement or by actual simulation; but these conditions before long cease to be deceptive. It is necessary to be provided with a sufficient variety of lenses, test-objects, and methods of examination; and any attempt at malingering would certainly soon be exposed by the contradictions and inconsistencies to which it would lead. But it must be remembered that a superficial knowledge of diseases of the eye is insufficient in dealing with such cases; the aid of an experienced oculist should be obtained before forming a definite opinion. *See VISION, Disorders of, from injuries of the head and spine.*

Treatment.—In severe injuries prompt treatment on the spot is of the first importance; arrest of hæmorrhage, relief of shock, and easy transport should be the surgeon's first consideration. The following printed directions have been issued by the London and North-Western and Great Western Railway Companies, and are in use at all stations for the instruction of the officials, accompanied by an Esmarch's elastic tube:—

Rule 1.—When a leg or arm is severely wounded there may be no bleeding. In this case raise the limb on cushions above the level of the body, and carefully watch the wounded part, so that the first bleeding may be seen.

Rule 2.—Should there be much bleeding, put on the elastic tube as soon as possible (see *Rule 3*); but if you have not got the tube near, raise the limb as high as you can above the body, and act as follows:—(a) If blood seems to come smartly from one part, place your finger and thumb firmly on that part, and stop up the place from which the blood is coming. (b) If you cannot see whence the blood flows, then roll up your handkerchief or cap, and with it press firmly over the bleeding part, not forgetting to keep the limb raised up.

Rule 3.—To put on the elastic tube, let the limb be held up as high as possible, then stretch the tube to the full, and wind it while stretched round and round the bare limb. When this is done, fasten the hooks at the ends to each other.

Rule 4.—The tube must be placed above the wounded part—that is, between it and the body. (a) When the leg or foot is injured apply the tube just above the knee; if the knee or thigh be wounded, then place it higher up on the thigh. (b) If the hand or wrist be wounded, put on the tube below the elbow; if blood come from the elbow or arm, then put on the tube higher up near the shoulder.

Rule 5.—If the limb be wounded so near the trunk that you cannot put on the tube, then you must do your

best to stop the bleeding by one of the plans named in Rule 2.

Rule 6.—If the injured person has to be carried far, either to a hospital or to a house, bear in mind—(a) To keep him warm with rugs or clothing. (b) To keep the limb continually raised on cushions. (c) To watch for bleeding. (d) Not to give too much brandy, especially if you have not been able to put on the tube.

Fractures may be treated by temporary splints made out of newspapers, the cushions of railway carriage-seats cut up; and straps and handkerchiefs or shirt-tails will make good bandages.

For the immediate relief of shock, avoid transportation to long distances: utilise cottages or buildings near the scene of the accident; insist on rest and quiet, and freedom from exciting interviews with friends; give diffusible stimulants or alcohol in moderation; also give hot coffee and beef-tea, when possible. For the treatment of nervous excitement after shock, bromide of potassium, in ten-grain doses, combined with the same quantity of carbonate of ammonia, may be given in an effervescent form with good effect.

Opium, chlorodyne, hydrate of chloral, &c., are usually contra-indicated, as they generally increase the nervous excitement. They should be given only in cases of severe organic injury, to relieve pain. With regard to operative measures, fractures and dislocations should be reduced at once, and, in injuries which require amputation, a primary operation is generally best. There is usually little chance of saving limbs, with comminuted and compound fractures especially, where joints are involved; and there is much risk to life in the attempt to do so. Of course, it is often necessary to wait for the first effects of shock to pass off.

The treatment of fright and emotional and functional illness is often a question of difficulty. It may be taken, as a general rule, that the less medicine given the better, and that as little fuss be made and as little anxiety shown as possible. But the surgeon is often in a dilemma. Many patients resent most vigorously any light estimation of their injuries, and any encouragement to resume work or get about is looked on as inattention or ignorance. Then, again, the friends usually interfere, and another and a more sympathetic doctor, so called, is recommended. It follows, therefore, that moral treatment is necessary. The confidence of the patient must be first gained by sympathy and attention, then he may be informed of the nature of the symptoms, and will more readily follow the necessary treatment.

The symptoms which most commonly require active treatment are dyspepsia, con-

stipation, and sleeplessness. For dyspepsia, a dinner pill containing a grain each of gray powder, euonymin, and powdered rhubarb may be given before each meal, and an effervescing saline with ammonia, after meals, is very efficacious for pain and flatulence. For constipation, by far the safest and most effectual drug is cascara sagrada. It does not debilitate nor depress the nervous system like saline aperients and mineral waters, nor is it followed by constipation, like most of the cathartics and other aperients. A very good formula is the following:—Liquid extract of cascara, f3j.; syrup, f3j.; maltine, f3ij. One or two teaspoonfuls to be taken before the evening meal or at bedtime, in water. For sleeplessness, it is a very bad plan to give large doses of bromide, and as for opium, morphia, chlorodyne, and hydrate of chloral, there is no surer way of retarding recovery than to give them. As the general symptoms of shock subside, sleep will return, and good nights may often be obtained by a glass of hot whiskey and water at bedtime or hot beef-tea or gruel. Many of the symptoms of nervous shock are much aggravated by the injudicious use of strychnine and iron. It is not unusual to find that large doses have been given from the date of the accident, generally with the effect of producing palpitation, twitching of limbs, sleeplessness, sensations of pins and needles, headache, and dimness of sight, all of which symptoms are immediately attributed to the accident, and any nervous shock that may have been sustained is thereby materially increased.

In cases of persistent nervous shock, leading to hypochondriasis, hysteria, and other neurotic symptoms, such as paralysis, hyperæsthesia, or anæsthesia, change of air and scene is a good remedy; but when this is recommended, the beneficial effect that would ensue is often retarded by the anxiety and officiousness of friends or relatives who accompany the patient, and never cease to talk of the accident or to enlarge upon his injuries. Again, it is common to find the nature of the symptoms misunderstood, and often escharotic liniments, blisters, and even the actual cautery, are applied.

There can be no doubt that, in such cases, treatment at a hydropathic establishment is most advantageous. Isolation from friends, change of scene and habit, absolute regularity in diet, freedom from stimulants and narcotics, are thus ensured, while there is every convenience for sedative local treatment by shampooing, massage, douching, and compress; and, lastly and most import-

ant, the attention of a medical man understanding the moral treatment of the patient is secured. There is a certain proportion of cases, however, where nothing but money compensation will do any good. Those persons are not always dishonest—the worry of impending litigation, or anxiety about business losses, may keep up the nervous state; others, knowing that pecuniary compensation is certain to be obtained, will not make the slightest effort to return to business and shake off lethargy and laziness.

In cases of concussion of the spinal cord or brain, of course the first necessity is absolute quiet and rest in bed, and, if there is no doubt about the correctness of the diagnosis, the surgeon should insist on a much longer rest than the patient is often disposed to take.

Where there is localised tenderness of the spine, stimulating liniments and unguents (especially oleate of mercury) do good. Blisters and the actual cautery may sometimes be applied with much benefit, but in hysterical and nervous cases they are not to be recommended. Where there are symptoms of inflammatory changes taking place in the cord, iodide of potassium and bichloride of mercury in small doses are beneficial. In spinal anemia it is found that iron, arsenic, strychnine, and quinine may be given with good effect, and, where paralysis has occurred from this cause, a course of galvanism with the slowly interrupted current should be tried. Where there are symptoms of meningeal inflammation of the brain or spinal cord, the writer has found grain doses of calomel and extract of aconite relieve pain and spasm in a marked degree. THOMAS BOND.

RANULA.—The term 'ranula' has been employed, somewhat loosely, to indicate the various sublingual cysts which project into the floor of the mouth by the frænum. Such a tumour may originate in many ways—by dilatation of one of the excretory ducts of the sub-lingual or sub-maxillary gland, by enlargement of the sub-lingual bursa of Fleischmann, or by cystic transformation of the connective-tissue interspaces of the part; or it may be dermoid or hydatid in structure. It is desirable, however, to exclude the two last, reserving the name 'ranula' for tumours having the characters about to be described, until the advance of pathology and diagnosis enables us to dispense with the expression altogether.

Symptoms.—The true ranula appears as a soft fluctuating tumour beneath the

tongue, on one or other side of the frænum, encroaching more or less upon the buccal cavity, and often projecting in a downward direction to give rise to a prominence in the sub-maxillary region. It is smooth, bluish, and translucent, of globular or ovoid form, and its surface is often traversed by Wharton's duct. The contained fluid is more or less viscous, tasteless, transparent, and of a tint varying from the palest straw to a deep brownish-yellow; and is occasionally discoloured by the admixture of blood or pus.

When small, it causes little inconvenience, but it may attain such large dimensions as to interfere with deglutition, articulation, and even with respiration. In one case mentioned by the elder Cline, the patient was on the point of suffocation in consequence of the backward displacement of the tongue by a huge ranula, when a timely use of the surgeon's lancet averted the danger. The tumour may appear at any age and in either sex, and can rarely be traced to any exciting cause.

Pathology.—It was once believed that the majority of cases of ranula were due to dilatation of a portion of Wharton's duct behind an impacted salivary calculus, but it is now certain that such a condition is very exceptional, even where a competent source of obstruction has been found; and some authorities have gone so far as to deny its existence altogether. The researches of Recklinghausen tend to show that the tumour is nearly always developed at the expense of the ducts of the sub-lingual gland, behind an inflammatory constriction or closure of the lumen of the tube. It is not, however, a mere dilatation containing an accumulation of saliva, but a true cyst, differing, both in its structural characters and the nature of its secretion, from the gland from which it is derived.

The cyst wall consists of a capsule of connective tissue with elastic fibres and vessels, usually delicate, but sometimes of considerable thickness ($\frac{1}{25}$ th of an inch), and lined with a double layer of epithelium, of which the superficial cells are cylindrical and ciliated; and chemical analysis of the fluid reveals the presence of mucus and albuminate of soda, but neither ptyalin nor sulpho-cyanide of potassium. With these peculiar features, it might be doubted whether the condition really arises in the manner described, but Recklinghausen has succeeded, in some cases, in discovering the orifice of the gland-duct in the wall of the cyst.

The share taken by Fleischmann's 'sub-lingual bursa' in the etiology of ranula is

still uncertain. This anatomical structure may be demonstrated without difficulty in many subjects, and there is no reason why, like other bursæ, it should not occasionally give rise to a cystic tumour; but it cannot be said that any ranula has ever yet been proved to originate in this manner. It is probable that, in a case of the kind, the character and composition of the fluid and the structure of the cyst-wall would be found to vary from the description just given, as that of the typical ranula.

Treatment.—As a preliminary measure, a careful search should be made, by palpation, for a calculus or other source of obstruction, which must be removed if found; but should nothing of the kind be discovered, the surgeon has the choice of several methods by which he may attack the tumour directly.

(1) Complete excision of the cyst. This method was recommended by Marchetti in the early part of the present century, and more recently by Schuli and others, but has seldom been carried into effect. It is necessarily the most radical procedure, and it is less difficult than might be anticipated, as the cyst-wall adheres but loosely to the adjacent tissues. The floor of the mouth must be fully exposed; and after freely incising the tumour in its long axis, the cyst may be removed, partly by traction, partly by small curved scissors. The administration of chloroform must usually be dispensed with, owing to the risk of entrance of blood into the air-passages.

(2) Removal of a portion of the cyst-wall with the superjacent mucous membrane. The operation rarely effects its purpose, owing to the speedy closure of the gap, and is now employed chiefly as a preliminary to other measures.

(3) The establishment of a permanent fistula to allow the continual escape of the contents of the tumour into the mouth. Louth endeavoured to achieve this end by repeated cauterisation of the edges of the opening left by an excision of a portion of the cyst, but without success. Dupuytren's *bouton à chemise*, as modified by Reisinger—a short canula with a button-like plate at either end—was an ingenious device to attain the same object. One extremity of the instrument was inserted into the cyst, the other remaining in the mouth, while the intermediate portion prevented the closure of the wound and provided an exit for the escape of the fluid. Chelius and others have expressed satisfaction at the results, but it has generally been found that the movements of the tongue rendered

it difficult to keep the implement in place. A simpler and most effectual method is the insertion of a loop of silver wire, which will lie quietly in the floor of the mouth and act as a permanent drain.

(4) The obliteration of the cyst by inflammation. For this purpose many plans have been essayed, including setons, the injection of iodine and other fluids, cauterisation of the interior of the cyst after the excision of a portion of the wall, and plugging the cavity with lint or other material, plain or steeped in iodine or chloride of zinc solution; but although a cure sometimes follows the means adopted, the general rule is failure, with the occasional addition of troublesome inflammatory complications in parts outside the limits of the tumour.

SUB-LINGUAL DERMOID CYSTS are not often met with. They may be diagnosed from true ranula by their congenital origin (of which, however, it is not always possible to obtain a history), their comparatively slow growth, their greater firmness of consistency, and, especially, by the absence of translucency. They usually tend to project chiefly in the direction of the sub-maxillary integument. The appropriate treatment is excision.

HYDATID CYSTS in the position of ranula are extremely rare. It might be difficult to distinguish their nature before operation without a microscopic examination of the contents.

SUB-LINGUAL ABSCESSSES AND HÆMATOMATA may generally be recognised without difficulty by the history of the swelling, except where the suppuration or hæmorrhage has occurred within the cavity of a ranula. In cases of doubt, the diagnosis may be established by the examination of a portion of the fluid drawn off by a small aspirator (morphia injection-syringe) or a trocar and canula.

W. ANDERSON.

RAYNAUD'S DISEASE. See ARTERIES, Diseases of; GANGRENE.

REACTION.—When a patient recovers from a condition of collapse, he passes on into the state known as that of reaction. The time that elapses between the oncoming of the collapse and the commencement of reaction varies according to the amount and intensity of the former. The stages of reaction are various. In some cases, the patient will rapidly pass from one to the other, so that complete restoration of the impaired faculties is brought about in a few minutes; in other cases, reaction is

slow and improvement almost imperceptible, and complete restoration does not take place for days or weeks.

The *symptoms* of reaction are as follows:—The patient, who has been lying motionless on his back, evinces a desire to change his position; in many cases he soon begins to retch, and perhaps vomits. The pulse improves in volume, tone, and rapidity; the respirations become deeper, and are often sighing; the clammy skin becomes warmer, and the lips assume a redder hue, swallowing is more easily accomplished; the mental faculties are gradually restored, the patient takes notice of surrounding objects, and is able to answer questions rationally. In some cases, complete restoration now ensues without further complication; but in others, after some hours, feverish symptoms supervene, the skin becomes hot and dry, the face is flushed, the eyes are bright, and the mental faculties are all in a state of excitement. The pulse becomes rapid and jerky, the respirations hurried; the patient is restless, and complains of thirst and headache. The temperature also rises to a varying extent. In this condition the patient may remain for a time, varying from a few hours to one or two days. Recovery is often by crisis, and after a long sleep complete convalescence may quickly ensue. In yet other cases, however, worse symptoms may follow, and a condition of 'prostration with excitement' may result; the rapidity and weakness of the pulse increase, respiration becomes gasping and hurried, the tongue is dry and tremulous, the patient becomes restless, and often wildly delirious, the temperature rises, and no sleep can be obtained. Exhaustion gradually supervenes, the pulse becomes running, the delirium becomes of the low and muttering variety, and the patient dies in a state of coma.

The above symptoms may be thus explained:—In consequence of the collapse induced by the injury, there is necessity for increased action of the various vital organs in order to preserve life. But, in consequence of the weakness induced by the same injury, there is a want of power in the organs on which the call is made. If the want of power be excessive and the need of action great, there results 'prostration with excitement'; if power be sufficient, a reaction which soon accomplishes its purpose will ensue.

Treatment.—So long as reaction is not excessive, there is no indication for treatment. If it be excessive or prolonged unduly, the indications are—(1) to support the

patient's strength; (2) to moderate the excessive irritability of the vital organs. With regard to the first, stimulants must be sparingly given, and reliance placed rather on strong fluid nourishment, and nutrient enemata if vomiting be troublesome. The second indication is fulfilled by perfect rest and quiet, keeping the head cool, and giving opium or morphia in doses which are sufficient to produce the required effect, but which must be regulated according to the requirements of the case. Hyoscyamus and belladonna are also useful.

ANTHONY A. BOWLBY.

RECTOCELE—Prolapse of the posterior wall of the vagina. *See* VAGINA, Affections of the.

RECTO-VAGINAL FISTULA. *See* VAGINAL FISTULÆ.

RECTO-VESICAL FISTULA.—A communication between the rectum and the bladder, with usually the result of an escape of feces or flatus into the bladder or urethra, or of urine into the rectum.

It may be congenital, or be caused by accident, operation, or ulceration. If the rectum be imperforate at birth, this condition is sometimes complicated by an arrest of development of the perineal septum between the bladder and rectum, so that a more or less considerable opening exists, through which meconium or feces can pass into the bladder. If a free passage can be made in the normal situation into the bowel, the abnormal communication may subsequently close. If such a passage cannot be made, or if the recto-vesical communication persist, when a free channel has been made for the feces in the normal situation, Littré's operation should be performed.

The rectum may sometimes be incised in the operations for lithotomy. It is said to happen more frequently than lithotomists are aware of. If so, the wound generally heals speedily. But, if a permanent fistula result, urine will escape into the bowel, and cause irritation and excoriation. Dilatation of the anus will probably bring the rectal opening into view. If it be very small, the application of the actual cautery will suffice, but if it be larger, the edges should be freshened and united by sutures, as in the operation for recto-vaginal fistula. The patient should maintain a lateral or prone position, and any accumulation of urine in the bladder be prevented until union has resulted. If this procedure be not successful, a grooved staff should be intro-

duced into the bladder, and by division of the intervening structures upon it a perineal fistula established. The wound will then heal by granulation.

A similar fistula occasionally resulted from the now seldom practised operation of tapping the bladder through the rectum, in retention of urine.

In malignant disease of the rectum, perforation from ulceration into the bladder may occur. Diversion of the fæces by the operation of lumbar colotomy would be the most suitable treatment; for the escape of fæcal matter into the bladder would probably induce cystitis, and might also give rise to retention of urine from obstruction of the vesical orifice.

Tuberculosis of the anal channel may sometimes result in recto-vesical fistula. Or the disease may originate in the prostate or vesiculæ seminales, and by ulcerating in both directions produce this condition. In this form of the affection, flatus rather than fæces may pass into the bladder or urethra, and urine may escape into the anal passage. The general condition of the patient must determine the propriety of operative interference. The establishment of a perineal fistula, by which the urine would constantly drain into a portable urinal, might give some relief.

JEREMIAH MCCARTHY.

RECTUM, Injuries and Diseases of the.

The anus, from its superficial position, is liable to injury, like the rest of the surface of the body, from contusions, burns, and scalds. These do not require any special treatment or description. The orifice of the anus may be lacerated by the passage of large and hard accumulations of fæces, or of bones or similar substances which have been accidentally swallowed. As a rule these heal spontaneously, but in unhealthy subjects, or if bathed in irritating discharges, they may ulcerate. Attention to cleanliness, removal of the source of irritation, and the application of mildly stimulating lotions or ointments will suffice for treatment. In tedious or instrumental labour, pressure on the recto-vaginal septum may result in sloughing and the formation of a recto-vaginal fistula. Or, in the final effort of parturition, the perinæum may be ruptured, and if the laceration extend into the anus, incontinence of fæces will result. For the description and treatment of these conditions, *see* VAGINAL FISTULÆ; PERINEUM, Rupture of the.

Maniacs, idiots, and persons of depraved or weak intellect, sometimes introduce

foreign bodies into the rectum, with more or less injury to the part. Medical literature abounds in instances of this kind. The writer met with a case where a man, in a drunken freak, had thrust an ordinary beer-glass, bottom upwards, into his rectum. It had passed beyond the sphincter muscles, which had firmly contracted. When he applied for relief, after an interval of some days, the rim of the glass was embedded in a deep ulcerated groove in the mucous membrane, which greatly increased the difficulty of extraction. Such cases must be treated according to the conditions of each case, and will sometimes tax to the uttermost the ingenuity of the surgeon. Rough, unskilful introduction of bougies or enema-tubes may sometimes result in perforation of the rectum. If the perforation be below the peritoneum, perirectal inflammation and suppuration will probably ensue. But if the peritoneum be perforated, and especially if nutrient or cathartic enemata have been pumped into its cavity, death from shock or peritonitis will be the most probable consequence. If the injury be recognised at the time, dilatation of the anus and the internal administration of opium and mercury should be employed.

For malformations of the rectum *see* ATRESIA ANI.

The mucous or submucous tissue of the bowel is exceedingly rarely the seat of a *navoid* growth. Only two instances of this condition have been recorded, for which reference may be made to the *Lancet* and *Medico-Chirurgical Transactions* for 1883. When ulceration occurs, hæmorrhage to an even fatal extent may result. We can only direct attention to the possibility of this condition, and the treatment must be regulated according to the circumstances of each case.

Pain, tenesmus, constipation alternating with diarrhoea, the discharge of mucus, sero-purulent or sanious fluid, or of blood in varying degrees and combinations, are symptoms common to most diseases of the rectum. But, however clearly the history may indicate the nature of the affection, thorough and careful examination of the part must always be made. Patients, especially women, are sometimes most unwilling to submit to this. A surgeon ought never to yield to this objection, however natural. The writer has met with cases where the patient's life had been rendered miserable and the health seriously affected, from treatment directed in accordance with the statements of the patient, and without

examination of the part. Even when the cause may be seemingly apparent, as in fissure, piles, fistula, or the like, careful investigation will sometimes ascertain that these are only secondary results of some lesion higher in the bowel, or of some disease of the bladder or urethra.

Sometimes, especially in women, paresis of the muscular coat of the bowel results from long-continued and neglected constipation. This is known as *atony* of the rectum. From lack of expulsive power, the rectum is enormously distended with flatus or fæces. Careful regulation of diet, and the internal administration of the extracts of *nux vomica* and *belladonna* will usually ensure a restoration of the normal condition.

INFLAMMATION OF THE RECTUM. *See* PROCTITIS.

INFLAMMATION OF THE TISSUES SURROUNDING THE RECTUM. *See* PERIPROCTITIS.

NEURALGIA OF THE RECTUM.—This may be defined as an abnormal excitability of the nerves or nerve-centres of the rectum, and the symptoms vary greatly. Sometimes, patients complain of pain in some parts of the rectum, paroxysmal or constant, unaffected by defæcation, for which no objective cause can be ascertained. Such patients are not infrequently of a markedly hysterical or hypochondriacal temperament, and, in the absence of any local cause, the treatment must be directed to the improvement of the mental condition. When there is no evidence of such disposition, the symptoms may possibly be due to a small exostosis pressing on some of the nerves supplying the rectum, or to some localised affection of the brain or spinal cord. The nervous condition of such patients should be carefully examined. The cases are, however, very rare, and the treatment must be modified according to the circumstances of each case. In other patients, this abnormal excitability may manifest itself by an almost irresistible desire to go to stool at unseasonable or impossible times, without any natural occasion. This has been designated by Curling as irritability of the rectum. As the intestine is now known to abound in many varieties of micro-organisms, by whose influence different decompositions are excited in the contents of the alimentary canal, it is not impossible that some specially irritating substance may be produced from such a cause in the secretions or contents of the rectum. Relief has been experienced, in such cases, by washing out the rectum with lukewarm water, and weak carbolie lotions

might be tried, together with the internal administration of salicylic acid, by which the development of such micro-organisms is checked. But the mental condition has also great influence in these cases, as sometimes the irritability ceases or greatly abates when the patient is assured that he can, if necessary, satisfy his desires.

POLYPUS OF THE RECTUM.—A new growth from the inner wall of the rectum. It is sometimes *papillary*, but more frequently *follicular*. The papillary form consists of elongated papillæ studded with secondary papillæ, usually sheathed with cylindrical epithelium and presenting a tuft-like appearance. The follicular variety is an outgrowth covered with mucous membrane, and has well-developed Lieberkühnian follicles. Muscular and fibrous elements also enter into its formation, and, according to the predominant tissue in it, the growth may be classed as adenoma, myoma, or fibroma. Adenoma and myoma are usually met with in children and young adults, while fibroma occurs more frequently in adults. It has been suggested that this is the result of time, and that the mucous membrane of the young growth may atrophy, and the residue become indurated by chronic inflammation.

The rectal polypus is generally solitary, but may be multiple, and may vary from the size of a raspberry to that of a hen's egg. It is very rarely larger than this, but the multiple variety may, in the aggregate, be large enough to obstruct the bowel.

The *symptoms* also vary. Sometimes a polypus is unnoticed during life, and only discovered by accident on the post-mortem table. Usually, however, it causes a mucous catarrh or hæmorrhage. Bleeding from the rectum after defæcation, in a young child, if there be no accidental injury to account for it, is almost certainly indicative of the existence of a polypus. If the peduncle be of sufficient length, the tumour may be protruded through the anus in defæcation, and is sometimes retained in that position by spasmodic contraction of the sphincter muscles. It is thus exposed to injury, and may ulcerate or become inflamed, and will always cause a disagreeable sensation as if some foreign body were lodged there. It is sometimes associated with ulceration of the mucous membrane of the bowel, especially with the variety known as fissure of the anus. It may also induce prolapse of the bowel or be complicated with internal piles. Sometimes an internal pile, indurated by chronic in-

flammation, is clinically indistinguishable from a fibrous polypus. In the multiple form, the mucous catarrh and hæmorrhage may be so great as to seriously impair the patient's health. This disease greatly resembles the villous growths which sometimes occur in the bladder. They are very rare, but are sometimes met with in more than one member of the same family. The growths present club-shaped protrusions, in some parts closely aggregated, in others more isolated. They are very vascular, and microscopically are found to consist chiefly of glandular tissue. See VILLOUS TUMOURS.

The *diagnosis* can only be assured by digital and ocular examinations. In the event of the polypus having an attachment high up in the rectum, the examination should always be made immediately after an action of the bowels, when the tumour will be found either protruding from the anus or within reach of the finger. It could only be confounded with an internal pile, from which the history, situation, and pedicle will sufficiently distinguish it, except in the case of an indurated pile, which is practically a polypus and requires the same treatment. The multiple variety is unlike any other disease of the rectum, and when seen cannot be mistaken.

Treatment, in all cases, consists in ligature of the pedicle and abscission of the growth. Removal without ligature might cause troublesome hæmorrhage. If the pedicle be thin and soft, caution must be observed in applying the ligature, as the pedicle might be torn across and bleeding result. In order to bring the growth within reach of the operator, an enema of warm water is sometimes requisite. In the multiple variety, the growths are sometimes so closely aggregated as to render necessary the removal of the portion of mucous membrane from which they spring. This may be either cut off with scissors or by the galvanic *écraseur*. The more isolated growths should be ligatured and cut off like the solitary polypus. The growths are usually so numerous as to require more than one operation for their removal. The after-treatment in such cases would be the same as for internal piles. The removal of a solitary polypus usually requires no subsequent treatment.

STRICTURE AND OBSTRUCTION OF THE RECTUM.—Stricture of the rectum is an impaired distensibility of some part or parts of this portion of the bowel, caused by structural changes in its walls or in the tissues immediately surrounding it. It must be distinguished from obstruction of the rectum, which may be caused by the

lumen of the tube being more or less completely filled by benign or malignant new-growths from its walls, or else compressed by similar growths from the neighbouring viscera or structures. As both impede or prevent defæcation, they may be treated of in the same article, although their origin and pathology are very different.

Stricture may be annular or tubular, and may be situated at the anal orifice, or at the juncture of the anus and rectum, or of the rectum and sigmoid flexure. These are the most usual situations, but it may be at any part of the rectum. It is usually single, and double stricture occurs very rarely. It may be of congenital origin. If the rectum be imperforate at birth, and if perineal dissection be requisite to expose the lower end of the bowel, stricture of the anal passage not infrequently results, and this is inevitable if the mucous and cutaneous surfaces cannot be united at the time of the operation. Stricture of the anal orifice may result from undue removal of the skin in operating for piles or prolapse, or from cicatrization of deep ulceration caused by disease or accidental injury.

Syphilitic ulceration of the bowel may by cicatrization induce stricture. If the ulceration continue, the reflex irritation produced by it will enhance the effect of the stricture. Such ulceration frequently occurs at the junction of the anus and rectum, and in the portion of bowel immediately above this junction, but it may occur at any part of the rectum. Any ulceration of the mucous membrane, whether simple, dysenteric, or tubercular, may have a similar result; but this rarely happens unless the deeper structures in the wall of the bowel have been involved in the process. Chronic catarrh of the rectum, with cicatricial contraction of the submucous coat may also cause it, and pelvic cellulitis, induced by disease or inflammation of the pelvic viscera, may be another exciting cause. It may also result from cancer.

When a stricture has existed for some time, the bowel above it becomes distended. Its muscular coats are hypertrophied, and the mucous membrane is very frequently ulcerated. If perforation of the bowel ensue, recto-vesical or recto-vaginal fistulæ may result, or, from peri-rectal suppuration, fistulous channels may open in the perineum or surrounding parts. If the stricture be above the anus, the mucous membrane in the lower part of the bowel usually becomes congested and inflamed. Mucous or purulent catarrh, piles, prolapse, and

anal fistulæ are then very frequent complications.

The earliest *symptoms* of stricture are constipation and difficulty in defæcation. But, as these conditions may result from many causes, a stricture may have existed for some time unknown to the patient. If it be inaccessible to ocular or digital examination, the *diagnosis* may present difficulty. The passage of ribbon-shaped motions was formerly regarded as a characteristic symptom. But if the stricture be at the upper part of the rectum, the motions, if there be any, will not have this form, and 'ribbon-shaped' fæces may be passed without the existence of any stricture, if the muscular structure of the rectum be unduly irritable. Constipation alternating with fluid motions, or the habitual passage of pellet-shaped fæces, are better indications. But these conditions may be due to obstruction as well as stricture. Bougies are sometimes deceptive. A fold of mucous membrane or the promontory of the sacrum may arrest the progress of the bougie, and induce the assumption of a non-existent stricture. It is sometimes useful to introduce a well-warmed and pliant O'Beirne's tube, and to pump some water into the bowel as the tube is advanced. It is, however, liable to coil upon itself, and so cause error. In doubtful cases, bimanual examination may be employed in adults with advantage. For this the patient should be placed in the lithotomy position and completely anæsthetised. The bladder having been emptied, the sphincters of the anus should be dilated, and the operator's left hand, well oiled, should be cautiously passed into the rectum. With the aid of the right hand pressed firmly into the left iliac fossa, the upper part of the rectum may thus be thoroughly explored.

If the passage be only moderately constricted, attention to diet and the use of laxative purgatives may enable the patient to live in comparative comfort. But if there be ulceration, the stricture will always be liable to inflammation, and by œdema and congestion of the mucous membrane may completely obstruct the passage. It has also a natural tendency to contraction, and may thus ultimately produce retention of fæces. If, in this condition, operative interference be delayed, ulceration and perforation of the distended bowel may result, and cause rapidly fatal peritonitis. This ulceration very frequently occurs in the cæcum. The treatment of stricture will vary with its position and cause. If it be at the anal orifice, a plastic operation,

planned according to the circumstances of the case, sometimes effects a complete cure. If it be in the lower part of the rectum, dilatation may be employed. For this, laminaria tents are very serviceable. A tent of suitable size, with a long firmly attached tape loop, should, when lubricated with glycerine, be passed into the stricture and left there for twenty-four hours. When it is withdrawn, the passage will be found to be greatly enlarged, and the introduction every second day of a gum elastic bougie, well softened in warm water, will prevent a recurrence of contraction. The size of the bougie may with advantage be gradually increased. The bougie should not be introduced by the patient or any inexperienced attendant, for ill-directed efforts have in some cases led to perforation and a fatal result. If there be ulceration, appropriate treatment must be employed. But if it be extensive, the patient's comfort and prolongation of life will be best attained by the operation of left lumbar colotomy. As a regular daily evacuation can then be insured without discomfort, and as the ulcer will no longer be irritated by the passage of fæces, the patient's health will improve, the local pain cease, and the diseased surface be placed under more favourable conditions for repair.

Lumbar colotomy is also the best mode of treating strictures at the upper part of the rectum, and so inaccessible for dilatation, if they cause retention of fæces; and for all strictures complicated by recto-vesical or recto-vaginal fistulæ, or by perirectal sinuses opening on the perineum or adjacent parts. In some cases, when colotomy has been performed for persistent retention of fæces in consequence of a stricture at the upper part of the rectum, motions will, after a short time, again pass through the rectum. This results from relaxation of the stricture when no longer irritated by the accumulation of fæces above it, and by the straining efforts to expel them. If the condition of the rectum be curable, the lumbar opening may be closed when occasion for it has ceased. But, as a rule, it causes very little inconvenience, which is cheerfully endured by patients who have experienced the discomfort and danger of retention or difficult evacuation of fæces.

Forceful dilatation of rectal strictures by specially contrived instruments, or by water pressure, is very dangerous. The incision of the stricture in one or many parts, though advocated by some surgeons, does not appear to be free from danger of pyæmia or perirectal inflammation. Recently, linear

proctotomy has been performed, with alleged good results, for simple strictures near the lower end of the rectum. For this purpose, a suitably curved trocar and canula should be introduced into the rectum, passed through the wall of the bowel above the stricture in the median line posteriorly, and through the cutaneous surface below the coccyx. The trocar having been withdrawn, the wire of an *écraseur* should be passed through the canula, and all the structures within the loop of wire slowly cut through. The galvanic *écraseur* may also be used for this purpose. The wound should be dressed in the ordinary way, and allowed to heal by granulation.

Obstruction of the rectum, due to growths within the bowel or to pressure from without, will cause symptoms similar to those of stricture. Very rarely, a large fibroid polypus may be the cause, or more rarely still some other benign growth. Syphilis may sometimes produce it by broad outgrowths from the mucous membrane. Cancer of the rectum is a frequent cause, and, in these cases, sometimes stricture and obstruction from new growths are combined. Malignant disease of the bladder, or uterus and ovaries, sarcoma of the sacrum, or even hydatid tumours, may occasion obstruction. When a fibroid polypus or other benign growth exists, it should be removed in the appropriate manner. Obstruction from syphilis should be treated with anti-syphilitic remedies, and, if relief be not speedily derived, colotomy should be performed. In obstruction from any other cause, colotomy will be necessary to relieve the immediate retention of fæces, and in some cases as a preliminary to further operations, such as excision of the lower part of the rectum. When the obstruction is due primarily to disease of the uterus, the possibility of obstruction of the cæcum or some part of the small intestine as well as of the rectum, should be remembered, and careful examination of the abdomen be made by percussion and palpation; so as if possible to determine whether left or right lumbar colotomy or enterotomy would be the most suitable procedure.

ULCERATION OF THE RECTUM.—The mucous membrane of the rectum is liable to ulceration from many causes. The passage and presence of fæces or flatus have no injurious effect on the normal mucous surface. But, if there be any lesion of this surface, the deeper structures do not possess this immunity, and may thus become the seat of inflammation and suppuration from the irritation of fæcal matter or of intestinal

gases. Simple ulcers may therefore result from wounds caused by fish-bones or the like, which have been accidentally swallowed, or by roughly introduced enema-tubes or other instruments.

Chronic catarrh may, by long-continued maceration, render the mucous surface liable to abrasion and so induce ulceration. The solitary lymphoid glands of the rectum are, like those in the other parts of the intestine, liable to inflammation and suppuration, and if the resulting abscesses burst into the rectum, funnel-shaped ulcers of minute size will result. These, if many in number and close together, may become confluent, and so cause destruction of a considerable extent of mucous surface.

Dysentery, tuberculosis, syphilis, and malignant disease of the rectum, frequently produce ulceration.

Leucorrhœal or other vaginal discharges may also cause ulceration of the anal orifice or passage.

Follicular, dysenteric, and tubercular ulcers are not limited to the rectum, and affect a more or less considerable extent of the rest of the intestine. They belong, therefore, to medical rather than surgical practice, and surgical interference is only required if perforation of the rectum has occurred, when pelvic cellulitis, ischio-rectal abscess, and perineal, recto-vesical or recto-vaginal fistulæ may result.

The *symptoms* of simple ulceration will vary with the situation of the ulcer. If it be at the orifice or in the anal passage, the patient will probably experience pain in defæcation, and there may be great spasm of the sphincter muscles. There will always be a discharge of muco-purulent or purulent fluid, and sometimes of blood. If the ulcer be above the anus, there will not usually be any pain, and the discharge alone will indicate that the condition of the part is abnormal. Digital and ocular examination must ascertain the cause. Sometimes, an ulcer may exist without the patient being in any way aware of it.

The *treatment* is sufficiently simple. Attention to diet, mild laxatives, and iodoform in powder or as an ointment, or cotton wool steeped in a two per cent. solution of nitrate of silver applied locally, will usually ensure healing. If there be much pain or spasm, forcible dilatation of the anus when the patient has been anæsthetised will produce temporary paresis of the sphincter muscles, and so expedite the case by relieving pain. If the ulceration result from chronic catarrh, the exciting cause

must be removed and then the above treatment employed.

Syphilitic ulceration may occur in any stage of the disease. The anal orifice or passage may be the seat of a primary sore from accidental infection or unnatural intercourse. It will cause pain in defecation, and may from irritation by faecal matter become very large. The induration and the indications of syphilis in lymphatic glands, &c., will render the diagnosis easy. Ordinary anti-syphilitic treatment will, with attention to cleanliness, suffice. Phagedenic ulceration must be treated, as elsewhere, by cauterisation with nitric acid or chloride of zinc, hot baths, poultices, tonics, and abundant nutriment.

The loss of tissue is considerable, and stricture of the orifice generally results. This must be treated by dilatation or a plastic operation, according to circumstances.

In the secondary stage, mucous papules in the anus or condylomata round it may, in unhealthy subjects, suppurate and produce extensive serpiginous ulceration. Iodide of potassium in five-grain doses, hot baths, iodoform in powder, and, if necessary, cauterisation with nitric acid will be the suitable mode of treatment.

In the tertiary stage, the lower part of the rectum is, especially in women, a frequent seat of syphilis. The submucous tissue may be uniformly infiltrated so as to produce rigidity and stenosis of the bowel, or gummata of large size may cause projections into the lumen of the tube, or numerous minute gummata may form and gradually extend for a considerable distance up the rectum. Ulceration of the mucous membrane speedily ensues. The patient will suffer from obstruction or stenosis of the bowel. The discharge of sanious, offensive fluid is abundant, and the pain is often very severe. Perforation into the vagina frequently occurs. The diagnosis is often very difficult. A history of syphilis or evidence of the disease in other parts of the body may indicate the nature of the case; but, when the distance is extensive, it does not yield readily to anti-syphilitic treatment. In such cases lumbar colotomy would be most suitable, and, the ulcerated surface being no longer irritated by the passage of faeces, would be more likely to heal. In less severe cases, irrigation with dilute Cond's fluid, and the internal administration of decoction of bark with biniodide of mercury, will be found beneficial. One-drachm doses of the liq. hydrargyri bichloridi, with five-grain doses

of the iodide of potassium, will be found to be a most convenient method of administering the biniodide of mercury.

MALIGNANT DISEASE OF THE RECTUM.—The mucous membrane of the rectum at, and for some extent above, its junction with the anus, is not infrequently subject to hyperplasia. This at first results in considerable enlargement of Lieberkühn's follicles, and, as secondary consequences of irritation, hypertrophy of the tunica mucosa muscularis and infiltration of the submucous tissue with leucocytes. The growth may be greater at some parts of the circumference of the bowel than at others, with the result of irregular projections into the lumen of the tube. There is also increased vascularity. If this be all, the growth is benign, and forms the superficial adenoma of Klebs. But, if the continuity of the membrana propria or basement membrane be broken through, and if the epithelial cells grow or pass along the lymph-channels among the component elements of the other structures of the bowel, it becomes true cancer. The immigrant cells form centres for new epithelial growths, which produce, by irritation, changes in the surrounding structures. These growths contribute to the obstruction of the bowel, and by pressure may produce atrophy and ulceration of the mucous surface. The disease may in this manner extend along the bowel, or invade the perirectal tissues and neighbouring organs, such as the vagina, prostate, or bladder. If perforation of the bowel ensue, ischio-rectal suppuration and perineal sinuses may result, or fistulous communications form into the vagina or bladder. The lymphatic glands in connection with the bowel, and the liver through the portal system of veins, may be the seat of secondary growths, and cancerous cachexia ensue.

If the irritative process predominate in the growths, scirrhus will result, with induration and contraction of the walls of the bowel. This variety of cancer does not occur frequently in the rectum. If the epithelial growths form the chief part, the cancer is soft or encephaloid. In this variety there is less induration and contraction, but the lumen of the bowel is obstructed by large, very vascular growths, which are sometimes of the cauliflower form and are very liable to slough. The epithelial new-growth tends to develop according to the type of the normal epithelium of the part from which it is derived. Microscopic examination of soft cancer of the rectum usually discloses, therefore, a

tubular structure, the tubules being sheathed with a single layer of cylindrical epithelial cells, and resembling Lieberkühn's follicles. This constitutes what is known as cylindrical-celled or adenoid carcinoma or epithelioma. Colloid cancer will result from the corresponding degeneration of the epithelium, so that elements of the new growth resemble boiled sago-grains embedded in the surrounding indurated tissues. Melanosis also sometimes occurs in the rectum.

The *symptoms* are at first very indefinite. As the disease is usually painless until ulceration has taken place, constipation and difficulty in defæcation are the first indications. When ulcers form, discharge of sero-purulent or sanious fluid or of blood will occur, but, if the case be complicated with piles, the source of the discharge may be mistaken. Careful exploration of the rectum should therefore be made in all cases of constipation or of purulent or other discharge from the bowel. When the growth presses upon the nerves of the sacral plexus, cramps and painful sensations in the lower extremities are often experienced. If the bladder or prostate be involved, there may be difficulty in micturition, and the passage of fæces into the bladder through a fistulous opening will very probably produce cystitis. As the ulceration progresses, pain in defæcation increases, and complete obstruction of the bowels often results; partly from the occlusion of the tube by growths or by contraction, and partly from the arrest of peristalsis, in consequence of the muscular fibres of the bowel being destroyed or impaired. The rate of progress will vary with the nature of the cancer. In the firm, contracting variety, it is much less rapid than in the encephaloid form.

Cancer of the other pelvic viscera may, by direct continuity, invade the rectum. In such cases, obstruction of the bowels will, so far as regards the rectum, usually be the chief symptom.

The anal passage is sheathed with squamous stratified epithelium, and the external orifice is abundantly supplied with anal glands. The epithelium of these glands, or of the rete mucosum, may be the starting point of new growths. When these have perforated the basement membrane, epithelioma of the anus is the result. It usually commences as a small nodule or wart, which has sometimes been mistaken for an external or intermediate pile. The surface, however, soon becomes fissured and ulcerated, and bleeding or sanious discharge results. The disease generally extends along the cuta-

neous surface round the anus, but it may also pass up the bowel, or in both directions simultaneously. Anal epithelioma is much more painful than rectal cancer. The pain during defæcation is very severe, and it is also more constant than in the rectal disease, and often radiates to distant parts.

The *diagnosis* of malignant disease of the rectum does not usually present much difficulty. Syphilitic ulceration is alone likely to be mistaken for it. The margin of the anus is sometimes from accidental infection, or from unnatural intercourse, the seat of a primary syphilitic sore. If this be of an unhealthy character, it may very greatly resemble an epitheliomatous ulcer. But anal epithelioma is usually an affection of advanced life, and primary syphilis would probably occur in younger persons. The history of the case, the presence or absence of other indications of syphilis, and the result of antisiphilitic treatment, in doubtful cases, should render the diagnosis certain. Syphilitic ulceration of the rectum is not so readily distinguishable from cancer. The lower part of the rectum is a frequent seat, especially in women, of tertiary syphilitic growths, which may be of sufficient size to considerably obstruct the tube, and when ulceration ensues the resemblance to cancer is very great.

Some writers suggest microscopic examination of shreds detached from the ulcerated surface as a diagnostic means; but while it might possibly corroborate a diagnosis formed on other grounds, in really difficult cases it would not be of much service, and the suggestion appears to be theoretical rather than practical. The history of the case, the general condition of the patient, and the effect of antisiphilitic treatment would form the best grounds for a diagnosis; and in bad cases, the palliative treatment of lumbar colotomy would be the same for both affections.

Treatment.—Anal epithelioma must be freely removed as in other parts of the body, unless the disease has progressed too far to admit of operation. If the growth be limited in size and superficial, it may be at once excised, and hæmorrhage arrested by ligature of vessels or by the actual cautery. Iodoform in powder would be the best subsequent application. But if the extent of the disease requires the removal of a portion of the anal wall, the passage should be forcibly dilated, and a curved incision of suitable extent should be made in the healthy skin corresponding in situation to the part that is to be removed. The dissection

should then be carried up through the perineal tissues, until the upper limit of the growth has been passed, and the diseased portion removed by the ordinary or galvanic *écraseur*, or with the knife or scissors, according to the circumstances of the case and the predilection of the operator.

When the anterior wall has to be removed, the introduction of a full-sized metal catheter into the bladder will be of service in indicating the position of the urethra and prostate gland. If the whole of the anus must be removed, the incision must be made correspondingly, and the isolated bowel excised with the *écraseur*. Some recommend the preliminary insertion of ligatures a little above the proposed line of excision, which may afterwards be used to unite the mucous and cutaneous surfaces. If this can be accomplished, the liability to subsequent stricture will be greatly diminished; but, as a rule, the tension of the parts is such as to cause the sutures to cut through and be useless.

Cancer of the rectum has latterly, owing to the enterprise of Continental and more recently of English surgeons, been treated by operation much more than was formerly deemed possible or justifiable. Experience has proved that three or four inches in length of the bowel can be removed with safety at the time of the operation, and with the result of complete cure in some cases, and of great amelioration in others. The indications for removal are that the upper limit of the growth should be accessible, and should not be so far from the anal orifice as to endanger wounding the peritoneum during the operation; and that the disease should be limited to the rectum and not involve the other pelvic viscera. The absence of secondary growths in lymphatic glands or in the liver should also, so far as possible, be ascertained. These conditions being fulfilled, an extension upward of the dissection required for removal of the anus until the upper limit of the growth has been passed, and the removal of the isolated bowel by the *écraseur*, would suffice. Attempts to unite the mucous and cutaneous surfaces are useless. Opening the peritoneal sac very seriously affects the chance of a successful result. In order to so far as possible prevent this occurrence, the bladder should be distended by injections of water, by which the recto-vesical fold of peritoneum would be considerably elevated. If it should be wounded, the aperture, if small, should be closed by a ligature, and, if large, a drainage-tube should be inserted,

and opium freely administered. In all such operations, and also when the whole or a large part of the anus is to be removed, lumbar colotomy is, in the writer's opinion, most advisable as a preliminary. When this has been performed, a daily painless evacuation can take place, the nutrition of the patient is not interfered with, the ulcerated bowel is no longer irritated by the passage of feces, or by the existence of fetid gases resulting from the fermentation of retained feces; and the wound caused by the subsequent operation is also free from such noxious influences.

In some cases, a portion only of the wall of the rectum will require removal. This can be accomplished after forcible dilatation of the anus, or division in the median line posteriorly of all the tissues from the mucous membrane to the skin, extending as high as the tip of the coccyx. The requisite portion of the rectum can be removed with scissors or the *écraseur*. Incontinence of feces is not very frequently a result of these operations.

In cases where removal of the growth is impossible, lumbar colotomy will be the best palliative treatment. Careful irrigation of the rectum, with carbolic acid solution or with diluted Condy's fluid, should also be employed. Scraping the ulcerated surface, and subsequently applying the actual cautery to it, are sometimes of service, and appear, for a time at any rate, to promote a growth of healthy granulation-tissue.

Sarcoma seldom occurs primarily in the rectum, but may invade it from other surrounding parts. It is not impossible that some of the recorded cases of encephaloid cancer may really have been sarcomata, in the days when the microscopic characteristics of both kinds of growth had not been so clearly distinguished as they have been in later times. The treatment would be the same as for cancer.

REFRACTION, Errors of.—In this article the following abbreviations are employed:—A., accommodation; As., astigmatism; D., dioptre; E., emmetropia; F_h, horizontal focus; F_v vertical focus; H., hypermetropia; M., myopia; V., vision;

+^{va}, convex; -^{va}, concave; <, less than; ', one foot or one minute; ", one inch or one second; ∪, combined with.—The function of the refracting apparatus of the eye is to bring rays proceeding from external objects to a focus on the sentient layer of the retina, and thereby give a distinct image of such objects. The calculation of the passage of rays of light through the various media of the eye—cornea, lens, &c.—is a very complicated one; in order to simplify it, it has been proposed to substitute for the actual eye a diagrammatic one consisting of a single refracting surface, bounded anteriorly by air and posteriorly by vitreous humour. The dimensions of such an eye have been fixed by Donders as follows:—Radius of curvature of the single refracting surface (the cornea) = 5 mm.; total length of the eye from cornea to retina = 20 mm.; distance of nodal point behind the cornea = 5 mm.; index of refraction = $\frac{4}{3}$. It will

be seen that the nodal point coincides with the centre of the cornea. This goes by the name of the 'reduced eye' of Donders; with it calculations about the optical properties of the eye are very simple, and the results are so nearly correct as to suffice for all practical purposes.

The relation between the refractive power and the length of axis of the 'reduced eye' is such, that parallel rays falling on the cornea are brought to a focus on the retina. Such an eye is called *emmetropic*, or is said to be in a condition of *emmetropia* (E.). This relation may be disturbed, so that the focus of entering parallel rays is either (1) anterior to the retina or (2) posterior to it; in the former case the eye is called *myopic*, or is said to be in a state of *myopia* (M.); in the latter the eye is called *hypermetropic*, or is said to be in a state of *hypermetropia* (H.).

In neither of these cases is a distinct image of a distant external object formed on the retina; the image of any point of such an object is not a point on the retina, but a circle of diffusion, the rays proceeding from the external point having come to a focus before reaching the retina in (M.), or being on their way to a focus behind the retina in (H.). In both cases the image of the external object is a number of overlapping circles of diffusion, and is therefore blurred.

There is a third anomalous condition of the eye, in which the image on the retina of an external point is not itself a point; this is the affection known as *astigmatism* (As.), which we shall describe later on.

These three departures from *emmetropia*—viz. *myopia*, *hypermetropia*, and *astigmatism*—are what we have to consider. They are often collectively described as *ametropia*.

Before the description of these affections a few words must be said about—(1) *the numbering of lenses*; (2) *the accommodation of the eye*; (3) *the determination of the acuity of vision*.

Numbering of Lenses.—Till a few years ago, lenses were numbered according to their *focal length*, generally expressed in inches, and the unit of measurement taken was a lens whose *focal length* was one inch, and whose *focal power*, therefore, being the reciprocal of the focal length, would be expressed by unity. Nearly all other lenses with which oculists have to deal are of a longer focal length than one inch, say twelve or twenty inches. The focal power of these lenses would be expressed by fractions $\frac{1}{12}$ and $\frac{1}{20}$ in the cases we have chosen for illustration. Working out combinations of these lenses necessitated much troublesome calculation of fractions. To avoid this, as well as other disadvantages, the *metrical system* of numbering lenses has been suggested, and is now almost universally adopted.

Here the unit of measurement is a lens whose focal length is 1 mètre. The focal power of this lens is called a *dioptre* (1 D); shortly, the lens itself is called a *dioptre*. A lens of twice the refractive power, and whose focal length is therefore half a mètre, is called 2 dioptres (2 D). A lens of half the focal power of the first will be .50 D, and have a focal length of 2 mètres, and so on. The focal lengths are better expressed in centimètres; thus the focal length of a lens of 1 D is 100 cm.; of 2 D, 50 cm.; and generally the focal length of a lens is found in centimètres by dividing 100 by the number of the lens in dioptres; and conversely the focal power of a lens is found in dioptres by dividing 100 by the number of centimètres in the focal length.

For example, take a lens of 5 D; what is its focal length in centimètres?— $\frac{100}{5} = 20$;

therefore the focal length is 20 cm.

Again, what is the focal power of a lens of 40 cm. focal length?— $\frac{100}{40} = \frac{5}{2} = 2.50$;

therefore the strength of the lens is 2.50 D.

Of course the signs + and - are prefixed to numbers denoting the strength of the lens according as the lens is convex or concave.

To convert from inches to dioptres is equally simple. Only English inches will

here be referred to. A mètre = 40 in. nearly; therefore a lens of 1 D has focal length of 40 in., and therefore a focal power of $\frac{1}{40}$, according to the old notation. A lens of 3 D is three times as strong as the first; therefore its focal power, according to the old notation, is $\frac{3}{40}$, and its focal length $\frac{40}{3} = 13\frac{1}{3}$ in.

The general rule is: to find the number of D in a lens, divide 40 by its focal length in (English) inches; to find the focal length of a lens in (English) inches, divide 40 by the number of D in the lens.

Thus a lens whose focal length is 12" is $\frac{40}{12} = 3.5$ D (nearly); and a lens of 7 D has

a focal length = $\frac{40}{7} = 6''$ (nearly).

In the following article lengths will, as a rule, be expressed in mètres and centimètres; occasionally the equivalent in feet or inches being given. It is useful to remember that, approximately, 1 mètre = 40";

1 cm. = $\frac{2''}{5}$; 1 mm. = $\frac{1''}{50}$.

ACCOMMODATION (A.).—All eyes have the power of increasing by a muscular effort their refractive power; this is known as the power of accommodation. This is not the place to discuss the physiology of the act; all we are concerned with is the measure of it. Donders showed that the amount of accommodation was independent of the refractive condition of the eye, and depended only on the age of the individual. It is very convenient to imagine that the eye, in calling into action its power of accommodation, takes to itself an auxiliary convex lens, the strength of which equals the increase of refractive power caused by the accommodative effort. This auxiliary lens ought, strictly, to be imagined as being placed in the position of the nodal point of the eye, but we may, without an error of practical importance, suppose it placed in front of the eye, in the position of an ordinary spectacle-glass. This way of looking upon accommodation, as a power residing in the eye of placing in front of itself a magnifying glass of suitable strength, will be found very useful when we come to examine the various errors of refraction.

The strength of this imaginary auxiliary lens is best expressed in dioptries.

The greatest amount of accommodation an eye can exert is called its *amplitude of accommodation*.

Donders drew up the following table of the amplitude of accommodation possessed by the eye at different ages:—

Age	Amplitude of Accommodation	Age	Amplitude of Accommodation
10 years	14 D	40 years	4.5 D
15 "	12 D	45 "	3.5 D
20 "	10 D	50 "	2.5 D
25 "	8.5 D	55 "	1.75 D
30 "	7 D	70 "	.25 D
35 "	5.5 D	75 "	0.00 D

In making the experiments on which this table is founded, the eye was tested alone, without the co-operation of the other eye. This is hence called the *amplitude of absolute accommodation*; when both eyes are uncovered, the *amplitude of binocular accommodation* is obtained. This is somewhat different from the results in the above table. See ACCOMMODATION OF THE EYE.

DETERMINATION OF THE ACUITY OF VISION.—The standard proposed by Snellen, and now generally adopted, is that a letter should be recognised, under proper illumination, when it subtends an angle of 5', the breadth of its limbs being one-fifth of its height, and therefore subtending an angle of 1'.

A scale of test-types has been constructed on this principle by Snellen. The scale consists of a series of rows of square Roman letters; each row has a number, which expresses in mètres the distance at which the letters in the row are seen under an angle of 5', and should therefore be recognised by a normal eye.

A special card is made for testing the sight at a distance so considerable that rays diverging from a point at that distance may be considered parallel. This card has seven rows of letters, which bear the numbers 60, 36, 24, 18, 12, 9, 6; it is most conveniently placed at a distance of six mètres (about twenty feet), that being the distance at which the letters of the row 6 should be made out. The acuity of vision (for which the symbol v is commonly used) is expressed by a fraction, of which the numerator is the distance at which the card is placed—viz. six mètres, and the denominator the number appended to the smallest row of letters which can be read.

Thus, if the smallest row of all is read, $v = \frac{6}{6}$; if row 12, $v = \frac{6}{12}$, and so on. If the types be placed at a different distance, it will be necessary to alter the numerator; for instance, if they be placed at four mètres, and the row 9 of the above card be the smallest read, $v = \frac{4}{9}$; at this distance we

have no types on the card small enough to express unity, which represents the standard of distinct vision; to do this, we should have to add to the card smaller letters still. It is immaterial what distance be chosen, so long as it is great enough for rays proceeding from that distance to be practically parallel; but six mètres, having come into general use, may be conveniently adopted for the sake of uniformity. Before the metrical system was generally adopted, distances were expressed in feet, and the numbers appended to the rows of letters correspondingly altered. Thus the row of largest letters was No. 200, the others being 100, 70, 50, 40, 30, 20.

In this case, the row of smallest letters being seen at twenty feet, v would be $\frac{20}{20}$

instead of $\frac{6}{6}$ as above; decreasing acuity

of vision would be expressed by $v = \frac{20}{30} = \frac{20}{50}$,

and so on, corresponding to $v = \frac{6}{9}$, &c.

In addition to the distance-test, eyes are often examined with smaller types at short distances; for this, Snellen's series may still be used; but the types of Jaeger are generally preferred. These are numbered 1, 2, 4, up to 20. In testing the sight, the number of the type that is read, and the distance at which it is read, should be noted.

It is necessary to ascertain not only what the unaided eye can read, but also what help lenses afford. For this purpose the surgeon should be provided with a case of test-glasses. This contains a series of pairs of convex lenses of increasing strength, from .5 D up to 20 D; a similar series of concave lenses, convex and concave cylindrical lenses, prisms, trial frames, &c. Each eye should be tested, and the result noted, separately.

It will be found a great saving of time to set to work methodically; the following procedure is recommended:—A trial frame is fitted on the patient's face, and an opaque disc placed in front of the left eye, so that the right eye is uncovered for testing. The patient is then invited to read Jaeger's No. 1, holding the types at any distance he chooses; if he fails to read Jaeger 1, he is tried with Jaeger 2, 4, &c., still at his own distance, till the smallest type he can read is found. This is noted, and also the distance at which he holds it for reading. Not much stress need be laid on this reading of *near* types as a test of acuity of vision; a presbyope, for instance, with perfect acuity of vision,

might not be able to read even large letters near at hand unaided by convex glasses.

The test is now continued with the *distant* types. And here it should be explained that, in ophthalmic works, a *distant* object means any object that is so far distant from the eye that rays proceeding from it may be considered to enter the eye practically parallel. This distance is conventionally put at about six mètres; in the following pages we shall then mean by a *distant* object an object at about six mètres.

The patient is accordingly invited to read Snellen's card of types placed at six mètres; he is told to begin at the row of largest letters, and read the other rows upwards or downwards as the case may be; the result is then noted. Further, the effect of putting + and - glasses in the trial frame is noted; but we must wait till the errors of refraction have been discussed before this effect can be appreciated. Suppose the patient reads Jaeger's 2 at 10", and at six mètres row 9; the result would be thus noted—

R.E. (right eye.)

J. 2 at 25 cm.

$$v = \frac{6}{9}$$

If we wished to examine the *near* vision more closely, we ought to find his near and far point. In the above case, for example, the patient might be able to bring J. 2 up to within 10 cm. of his face, and still read it, or remove it to 30 cm., and still see it.

This might be noted thus: J. 2, 10 cm.—30 cm. In finding the far point, care must be taken to test the eye with print adapted to the distance of that point from the eye. Thus, J. 1 is too small to be seen by an eye of good visual acuity at a greater distance than 35 or 40 cm. Beyond this distance larger print must be used. *See VISUAL ACUITY.*

The various errors of refraction may now be discussed; these being (a) *myopia*, (b) *hypermetropia*, (c) *astigmatism*.

(a) *MYOPIA*.—Here parallel rays come to a focus in front of the retina. This may arise either from an increase of refractive power in the dioptric apparatus of the eye, the entering parallel rays being consequently bent more abruptly, or from an increase in the length of the eye. It is usually due to the latter cause—the axis of the eye is too long. It is convenient, however, to consider it as depending on an increase in the refractive power of the eye; as it is only the *relation* between these two factors that we are concerned with, this way of viewing the matter is practically correct

We say, then, that in M. the refractive power of the eye is too great. We may imagine that a myopic eye is an emmetropic eye armed with a convex lens in front of itself, just as we did in considering accommodation. The strength of this hypothetical lens will then express the amount of M. For instance, in M. of 4 D, this lens is 4 D; this will make parallel rays diverging from its principal focus—i.e. from a distance of $\frac{100}{4}$ cm.; such parallel rays entering, then, the emmetropic eye, which we have considered combined with the convex lens to form the myopic eye, will be brought accurately to a focus on its retina, and therefore an external object, at a distance of $\frac{100}{4}$ cm. from this myopic eye, will be seen distinctly. Objects at all other distances will be seen indistinctly, so long as the accommodation of the eye remains at rest.

A myopic eye, however, has the power of accommodation like any other eye; this power, we have seen, is equivalent to placing in front of the eye a convex lens, of the strength necessary to focus on the retina rays from any object which such an eye can possibly see. It is evident that all objects situated farther from this myopic eye than $\frac{100}{4}$ cm. are out of its range of distinct

vision. Rays from such objects are already brought to a focus in front of its retina; the calling into action of the power of accommodation would only bring them to a focus still farther in front of the retina, and consequently make the images more blurred. It is different, however, with objects situated nearer the eye than $\frac{100}{4}$ cm.; rays from

such objects unite behind the retina, and an appropriate convex lens will bring them exactly to a focus on it; this lens the eye, bringing into play its accommodation, automatically selects when a distinct image of such objects is desired. There is a limit, however, in this direction also. An eye has at its disposal only a certain amount of accommodative power, expressed by a convex lens of a certain number of dioptries; this must not be exceeded.

An example may make this clearer. Keeping still to the eye with M. = 4 D, let us suppose that the amount of accommodation at its disposal = 6 D. Then, with A. altogether in abeyance, the eye will see distinctly only objects at a distance of $\frac{100}{4}$ cm. Suppose now it calls into play 2 D of its A.; it is then

in the position of an emmetropic eye with a lens = +6 D in front of it [4 D for the M. and 2 D for the A.]. The eye then will see objects distinctly at a distance of $\frac{100}{6}$ cm. If 5 D of its A. be used, objects will be seen distinctly at $\frac{100}{4+5} = \frac{100}{9}$ cm.

If the whole of A.—i.e. 6 D—be called into use, the only distance of distinct vision will be $\frac{100}{4+6} = 10$ cm. This is the nearest point of distinct vision. The farthest point of distinct vision is, as has been shown above, $\frac{100}{4} = 25$ cm. This eye, then, has a range of distinct vision between the distances of 10 cm. and 25 cm. measured from itself.

The nearest point of distinct vision is called the *punctum proximum*, or *near point*, and its distance from the eye is denoted by P; the farthest point of distinct vision is called the *punctum remotum*, or *far point*, and its distance from the eye is denoted by R; R-P is then the distance over which the eye has distinct vision, and $\frac{100}{P} - \frac{100}{R}$ = the number of D in the amplitude of accommodation [P and R being expressed in cm.].

Moreover, the lens which expresses the amount of M. is that whose focal length = R, and which therefore = $\frac{100}{R}$ D.

Etiology.—M. does not often appear before the eighth or ninth year; it generally progresses till adult age is reached. It is frequently hereditary, but may be induced by constant use of the eyes on very fine work, as that of watchmakers, &c. It is relatively common amongst the more civilised communities, and the more studious sections of those communities. M. occurs very frequently in those who have had defective sight from childhood; this is probably due to their constantly bringing objects close to the eyes, in order to get large retinal images. Any disease which causes increased curvature of the cornea will also cause M.; the most remarkable instance of this is 'conical cornea.'

The amount of M. varies within wide limits; up to 4 D would be called a low grade; 10 to 12 D is a pretty high amount, but much higher degrees occur—up to 20, 25, and even 30 D. The amount is often not the same in both eyes.

Symptoms.—In the low degrees, the only inconvenience is, usually, that the patient

cannot distinctly see distant objects. For near ones the sight is uncommonly good; in looking at distant things the myope partially closes the eyelids in a very characteristic manner; in this way he is able to narrow the circles of diffusion, and thus get a more distinct image.

In the higher degrees, the eye is seen to be decidedly too prominent; the patient complains of aching of the eyes on working, especially by artificial light; there is a constant feeling of tension; sometimes severe headache; flashes of light and *muscæ volitantes*. All these troubles are generally the greater the higher the degree of M.; they are worst of all when M. is rapidly increasing. In the high degrees there may be considerable diminution of the acuity of vision.

Diagnosis and Measurement.—If distant vision be improved by concave glasses, it is generally speaking a case of M.; sometimes, however, H. simulates M. This will be referred to later on. In examining a case where M. is suspected, it is most convenient to test the vision for near objects first. If the patient complains of very defective distant vision, whilst No. 1 of Jaeger's test types is read close at hand, it is almost certainly a case of M. To estimate the amount of M., find the *punctum remotum*—i.e. find the greatest distance at which the patient can read Jaeger 1 or 2. We have seen above that r is the focal length of the lens that measures M. Suppose, for instance, $r = 20$ cm.

$$\text{Then } M. = \frac{100}{20} D = 5 D.$$

But the accurate estimation of M. must be made with Snellen's large test-types at 6 mètres. A myopic eye, we have seen, may be regarded as an emmetropic eye armed with a convex glass, the strength of which is a measure of the M. We know the strength of this hypothetical convex lens, if we know the concave lens that neutralises it—i.e. brings the eye into the condition of an emmetropic one. Now the characteristic of an emmetropic eye is that it brings parallel rays to a focus on its retina, and therefore, if healthy, has the normal acuity of vision for distant objects, i.e.—has $v = \frac{6}{6}$.

We find, then, the weakest concave lens, which in the case of the myopic eye gives $v = \frac{6}{6}$; and this lens gives us the amount of M. It may be that no concave lens brings v up to $\frac{6}{6}$; in this case there must

be some other condition complicating the M.; some astigmatism, perhaps, or some degenerative change in the retina. Here we find the weakest concave lens, which gives the *best attainable acuity of vision* at 6 mètres, and this we take to be a measure of the M. It must be the *weakest* concave lens; with a stronger concave lens v might still be as good, but the lens would not represent the amount of M.; accommodation would be called into play to the amount necessary to correct the excess of strength of the lens; and this latter would represent not only the M. of the eye in a state of rest, but also the amount of accommodation so exercised. Take, for instance, an eye for which, with the small types, we find $r = 15$ cm.

This would give as a rough estimate $M. = \frac{100}{15} = 7 D$ nearly. We put up $-7 D$

in the trial frame, and find $v = \frac{6}{9}$; we hold up in front of this glass an additional $-1 D$; we now find that $v = \frac{6}{6}$. M. then $= 8 D$.

If now we put up $-8 D$ in the frame and hold an additional $-1 D$ in front of this, we may still find that $v = \frac{6}{6}$. It would

be an error to say, however, that $M. = 9 D$. What happens when we put up this additional $-1 D$ is this: $-8 D$ has brought the parallel rays coming from the test-types accurately to a focus on the retina, as is proved by the fact that with this glass the eye has the standard acuteness of vision; when $-1 D$ is put up in addition, it makes these parallel rays divergent. To focus these on the retina the eye must increase its refractive power to the extent of $1 D$, and this it does by unconsciously calling A. into play to that extent.

If we were to put up $-11 D$ in the trial frame we should still probably get $v = \frac{6}{6}$; in this case $3 D$ of A. would be in action, neutralising the excess of $3 D$ in the concave glass. In fact, a concave glass correcting the *apparent* M. of an eye may be supposed to be made up of two parts, one of which corrects the *real* M., the other of which neutralises the amount of A. called into play. The former part is a fixed amount; the latter varies and equals the excess of strength of the glass. We cause the latter to disappear by making the excess of strength of the glass to disappear—i.e. by finding the *weakest* glass, which gives the best attainable distant vision.

To resume: the measure of M. is the weakest concave glass which gives the best attainable distant vision.

This is the most convenient test of M.; but there are others to be applied with the ophthalmoscope, which must be briefly noticed.

In looking into a myopic eye with the ophthalmoscope, the mirror being held at a considerable distance from the observed eye, an inverted image of the fundus is seen. This is formed in the air in front of the eye at its *punctum remotum*. To see it, the surgeon must be farther off the patient than this *punctum remotum*. When the observer, still having the fundus image in view, makes slight lateral movements of his head, the image moves in the opposite direction. As he approaches the patient's eye, this image gets blurred, and then disappears; when he gets the ophthalmoscope into the ordinary position for direct examination, no distinct view of the fundus is obtained unless a concave glass is used behind the mirror. The *weakest concave* glass which gives a distinct view of the fundus in this position equals the amount of M. See OPHTHALMOSCOPY.

This is only the case, however, if the eye of the surgeon be in a state of emmetropia at the moment the examination is made. If he be myopic, the amount of his M. must be *deducted* from the concave glass, in order to get the amount of the patient's M. If he be hypermetropic, and have his A. relaxed, the amount of the H. must be *added*.

In retinoscopy the shadow moves with the mirror, unless M. be of very low degree—say less than 1.50 D.

Complications.—These attend the higher grades. The most common is what is called a 'posterior staphyloma;' this is, anatomically, a bulging of the coats of the eye in the neighbourhood of the optic disc; the pathogeny of it is uncertain. It may be well marked, so as in the enucleated eye to be easily recognisable as an ovoid protuberance. It is accompanied by atrophy and irregular pigmentation of the surrounding retina. With the ophthalmoscope, it is generally seen as a crescentic patch of atrophy extending along the outer margin of the disc; as it extends it embraces still more of the disc, and may reach outwards to the macula; or further, assuming then the most irregular forms. It lengthens still more the already elongated eye, and so increases the M. when it extends to the macula, that it seriously impairs v. This patch of atrophy is known as the 'myopic crescent.'

Other complications are fluidity of the vitreous with floating opacities, detachment of the retina, and divergent strabismus.

The latter is a much rarer attendant of M. then convergent strabismus is of H.

Treatment.—Much may be done in the way of preventive treatment by securing good school arrangements, proper lighting, well-constructed desks, &c.

When M. is already developed, what may be called the hygiene of the eye should be carefully attended to. Myopic children should not be subject to educational over-pressure, should not use their eyes up to the point of making them ache; if there be much irritation or fatigue about the eyes, prolonged absence from school should be insisted upon. It is right that M. should be taken into account when the time comes for the choice of a profession.

In all cases we must prescribe well-printed books and good illumination of them. The most comfortable artificial light is a good oil lamp, well-shaded, so that no direct light falls on the reader's eyes; in writing, the lamp should be placed on the writer's left front, so that the shadow of the pen may not interfere with the view. Books or writing must be held at a good distance, and stooping avoided. Frequent rest must be given to the eyes, and if they are irritable the cold douche may be used.

The optical treatment of M. is quite easy in the *low grades*, say up to 4 D. Here, all the patient complains of is that distant vision is imperfect; he can see to read and work quite well, his far point lying beyond the distance at which this can be done with comfort. Here, the glasses that fully correct M. may be ordered.

As these are intended only for distant vision, and therefore for occasional use, they may be worn in a frame or a *pince-nez*, as the patient chooses.

They are to be worn solely as a matter of convenience, and not as being at all necessary to the well-being of the eyes. Patients often want glasses especially for music. Pianoforte music lies usually at about 20" from the eye; if M. be not greater than 2 D, the far point of the eye being in that case not less than 20", no glasses are wanted; if M. be greater than 2 D, glasses will be necessary, and the full correction may be worn.

In M. of medium grade, say 4 D up to 8 D, as a rule glasses will be wanted both for distance and for reading; the distance glasses are a matter of convenience, as in

the lower grades of the affection. But reading glasses *must* be worn; without them, the strain on the eyes caused by the excessive convergence of the visual axes necessary for reading will certainly increase M., besides giving rise to much immediate trouble, aching of the eyes, and the other discomforts that have been already spoken of as attending the higher degrees of M. The distance glasses will be the full correction as before, and if the patient be young, and A. therefore good, the same glasses may do for reading. In these cases, however, A. has so long been in abeyance prior to the use of glasses, that it cannot be expected to be so active as in an emmetrope. As a rule, however, we may at first order that the distance glasses should be used for reading also; if no discomfort ensues, they may be continued in use; if, however, they cause pain, a somewhat weaker pair must be ordered for close work. For instance, suppose a patient with $M. = 8\text{ D}$; here $R = \frac{100}{8}$

cm. (4 inches). There is no distinct vision beyond 4 inches, and, further, vision at that distance is probably irksome on account of the excessive convergence necessary to bring both visual axes to bear on the same point.

Here 8 D should be ordered for distance, and in suitable cases also, tentatively, for reading and working. As 8 D brings the eye into the condition of an emmetropic one, the amount of A. necessary for reading

at 25 cm. ($10''$) will be $\frac{100}{25} = 4\text{ D}$. Now it is found by experience that, for continuous work, only about one-half of the full amount of A. at the disposal of an eye can be comfortably exerted. The ciliary muscle is in this respect like other muscles; it cannot exercise its full power for a long period without fatigue. The eye we are considering ought then to have 8 D of A. at its disposal, in order to read comfortably with the glasses; the table above given will show whether the patient's age is such that this amount of A. may be expected. Something also must be allowed for the fact of the eye being a myopic eye, and therefore not in the habit of using its A.

Say the patient's age is twenty. The table shows that at twenty the eye has 10 D of A.

This eye, then, will have the necessary amount of A. (8 D) for continuous reading, and still a reserve of 2 D . This may be called, then, a suitable case for ordering, experimentally, the full correction for both

distant and near use. If after a week or two's trial the glasses cause pain, a weaker pair may be ordered for reading; the deduction commonly made is 2 D , so that we should now prescribe -6 D for reading, the full 8 D being still used for distance. In wearing -6 D for reading at 25 cm. ($10''$) what demand is made on A.? We have seen that with the full correction -8 D , 4 D of A. is wanted; with -6 D , only 2 D of A. will be required. The eye ought then to have a total A. $= 4\text{ D}$, or rather more as it is a myopic one, say 5 D . Now, the table shows that A. does not reach so low a stage as 5 D till the age of 40 is approached. Hence, up to this age the glasses above suggested may be expected to suit the patient. Or, it may be advisable to order the glasses in a different way; if the patient's occupation be principally about things that lie near him, the weaker glasses may be used pretty constantly, and when very distinct distant vision is wanted, additional glasses that represent the difference between these weaker glasses and the full correction (in the above case -2 D) may be held up in a *pince-nez* before the other glasses in a frame.

The same rules apply to the higher grades of M. above 8 D . They must, however, be taken as only suggesting the principles to be followed. In no other affections of the eye is it more necessary to treat each case on its own merits.

It is principally in these high grades of M., but to some extent in the medium grades also, that all the discomforts described above are found. V is here nearly always much impaired, on account of changes in the fundus; the glasses necessary to remove the far point to a safe distance diminish the retinal images, and still further impair V. The patient is then tempted to hold his work near again, and then all the evil results of excessive convergence again ensue. If the struggle for binocular vision is given up, and one eye remains in a condition of divergent squint, the patient is often in a better condition. The diverging eye, it is true, suffers and may become amblyopic, but the other one is more comfortable. In addition to the best optical aid that can be given, all the hygienic measures recommended as general treatment should be put into force; if M. be rapidly increasing, and the symptoms of irritation severe, complete rest must be insisted upon, and the eye well protected from light; further treatment might consist in the use of flying blisters on the temples, or even occasional wet cupping with Heurte-loup's artificial leech.

(b) **HYPERMETROPIA.**—Here parallel rays come to a focus behind the retina. This is due to a disturbance of the normal relation that exists between the length of the eye and its refractive power. Actually, it is generally the case that the axis of the eye is too short; we shall, however, consider it as being due to a *decrease* in the refractive power of the eye, just as we considered M. to be due to an *increase* in this power. We may imagine that in H. we have an emmetropic eye armed with a concave lens in front of it. The strength of this lens will be a fair measure of H., since it represents the departure from the emmetropic eye.

Let us examine the peculiarities of vision in H., and suppose, for example, we have an eye with H. = 6 D.

This is equivalent to an emmetropic eye with a lens -6 D in front of it. Now this lens will make parallel rays to proceed as if they diverged from its principal focus—i.e. from a distance $\frac{100}{6}$ cm. in front of it.

These rays falling on the emmetropic eye, which we have imagined combined with the concave lens to form the hypermetropic eye, will not be focussed on its retina; only an emmetropic eye can focus parallel rays on its retina while the accommodation is at rest. Hence, distant objects, from which such parallel rays emerge, will not be seen distinctly by the hypermetropic eye. Still less will near objects be seen distinctly. The only rays that can be focussed on the retina in this case are rays which are parallel after having passed the hypothetical concave lens, and which therefore are converging virtually to its principal focus—i.e. to a point $\frac{100}{6}$ cm.

behind it. But the rays which proceed from all objects are divergent rays; hence, the hypermetropic eye, being able to focus on its retina only convergent rays, cannot (unassisted) see any external object distinctly. This is only so long as it remains at rest. When it calls into action its accommodative power, which, as we have seen, is equivalent to placing a convex lens in front of it, it can not only neutralise the hypothetical concave lens which represents its H., and so see distant objects distinctly, but, by a further tension of A., it can adapt itself for divergent rays, and so see near objects plainly. Suppose the above eye, for instance, in which H. = 6 D belongs to an individual ten years old. At ten our table shows that the total A. = 14 D. By exerting 6 D of his A., then, this person neutralises his

H., and brings his eye into the position of an emmetropic one, and has still 8 D of A. in reserve.

In this condition he sees distant objects distinctly. If he wishes to see near objects, he makes a further demand on his A., the amount depending on the distance of the object. Suppose the object is at 25 cm.

(10') from the eye: a convex lens of $\frac{100}{25} = 4$ D

at the eye would make rays diverging from the object parallel, and therefore in a condition to be focussed on the retina of the eye, which by using 6 D of its A. is already in a condition of emmetropia; the additional call upon A. then = 4 D, and the total amount of A. required by this hypermetropic eye for seeing distinctly at 25 cm. is 10 D. Will this eye be able to work for long at this distance? No; we have seen above that, for continuous work, not more than half A. must be in use; here 10 D—the whole of A. being 14 D—is in use. The eye, then, if called upon to work for long at this distance, would tire. An emmetropic eye, on the contrary, at the same age, having 14 D at its disposal, and not requiring to use any of this to correct any H., would want only 4 D out of the 14 for working at this distance, and would therefore do it easily. This fatigue of the eye on working is the type of the complaints of the hypermetrope.

Etiology, &c.—H. is always congenital, and never increases in after-life except slightly in old age; it may diminish, and even change into M., owing to elongation of the eye. After removal of the lens in the operation for cataract, a high grade of H. is produced owing to loss of refractive power: this is called aphakia. The amount of H. varies within wide limits; 2 or 3 D is a very common amount; 8 D would be thought a highest degree; in aphakia in an originally emmetropic eye H. equals about 10 D. The amount of H. in the two eyes is usually nearly the same.

Symptoms.—In low degrees there are often no symptoms till the patient approaches middle life; then, several years before people usually want spectacles, he comes with the usual complaints of presbyopia; cannot see to read, especially by artificial light, &c.

The age at which these symptoms occur depends on the amount of H. and the distance from the eye of the habitual work. At the age of thirty, for instance, total A. = 7 D, and therefore 3.5 D can be exerted continuously.

Now, for continuous work at 40 cm. (16") an emmetropic eye requires $\frac{100}{40} = 2.50$ D

of A. Suppose the person of thirty years of age has 1 D of H., then 1 D of his 3.5 of available A. will be used up in correcting the H., and the remainder 2.5 D will just suffice for continuous work at 16". Such a person would in a year or two probably need spectacles for his usual work.

In the higher degrees, even young people suffer much. Often the break-down of the general health determines the onset of the symptoms. In very high degrees M. may be simulated: distinct images being in no way attainable, objects are held very close so as to get large retinal images, and hence the patient is supposed to be short-sighted. In old people who have never worn glasses, and have a considerable amount of H., vision for near and distant objects may be so defective that the surgeon may, if he neglect to try the effect of convex glasses, diagnose some serious nerve-affection.

Diagnosis and Measurement.—The complaints of the patient usually indicate pretty clearly what is the matter. His 'eyes are weak'; close work soon tires him; the letters run into one another, get dim, &c.

We now proceed to test v in the usual manner, trying each eye separately, and both with near types and distant.

If v for distant objects be improved, or even not made worse by a convex lens, it is a case of H.

The amount of H. is given by the *strongest convex* lens which gives the best attainable vision at 6 mètres. It must be the *strongest* convex lens, in order to secure the complete relaxation of the accommodative power. Contrast this with the rule for M.; there it was the *weakest concave* lens which gave the best attainable vision at 6 mètres. A short consideration analogous to the one set out in the case of M. will show the reason of the rule in H.

There is, however, a difference in the case of H. Here, as we have seen, some amount of A. is always in play, even for distant vision, and a considerably larger quantity for near vision. The result of this is that the ciliary muscle gets into a condition of spasm, and will not relax when its continued contraction is no longer wanted, nay even is injurious to distinct vision.

Suppose $H. = 4$ D, and that glasses have never been worn; here 4 D of A. has always been in use for distant vision, and 7 D or 8 D

for near vision. In testing the eye now with the types at 6 mètres, probably $v = \frac{6}{6}$ without any lens at all, the 4 D of A.

being in action; 1 D is put up in the trial frame; as the eye will bear only +4 D in front of it for distant vision, 1 D of A. must

be relaxed if v is to remain $= \frac{6}{6}$. Suppose

v remains unimpaired, +2 D is now put up in the trial frame; if v is now to remain $= \frac{6}{6}$, another 1 D of A. must be relaxed.

If now the ciliary muscle be in the condition of spasm, it may refuse to relax this additional 1 D, even though strongly solicited to do so by the desire of the eye for distinct vision. If it do not so relax, 1 D would be the strongest convex glass that gave the best attainable vision at 6 mètres, and so 1 D would appear to be the amount of H., whereas H. is really = 4 D. In such a case as this, the total amount of H. would probably only appear when atropine or some such agent was used to thoroughly relax the ciliary muscle. The total amount of H. revealed after the prolonged use of atropine is called H. totalis (H. t.); the amount of H. that reveals itself when convex glasses and no atropine are used is called H. manifesta (H. m.); the difference between the two is called H. latens (H. l.). A small amount of H. l. is always present; it is only when it exceeds 2 D or 3 D that this formal distinction between H. t. and H. m. is made. When H. is written unqualified, H. m. is meant.

Ophthalmoscopic Tests.—In looking into a hypermetropic eye with the ophthalmoscope, at a considerable distance from the observed eye, a real image of the fundus is seen. This does not disappear as the patient is approached. When slight lateral movements of the surgeon's head are made, the image of the fundus moves in the *same* direction. When the surgeon gets the ophthalmoscope into the ordinary position for direct examination, the image is still plainly seen, and continues clear when convex glasses are used behind the mirror. The strongest convex glass with which the fundus can be distinctly seen is a measure of the H. (if the surgeon be himself emmetropic).

In retinoscopy the shadow moves against the mirror. It does so also in low M.

Complications.—The only one that need be mentioned is concomitant squint, which is nearly always convergent. See STRABISMUS.

Treatment.—This is simple and very successful. In ordinary cases it is enough to give glasses that neutralise the H.m.

If after a time there should be pain with these, the existence of a considerable amount of H.l. should be suspected. To get at once to the bottom of the case, atropine should now be ordered, and H.t. found. If this differ much from the H.m. originally found, fresh glasses should be ordered. These should be about 1 D weaker than the full correction, to allow for the inevitable slight spasm of accommodation, which will come on as the effect of the atropine wears off.

These glasses need generally be worn only for close work.

In high grades of H. it is best to give the full correction, and order the glasses to be worn constantly. This is especially desirable in children.

In the case of old people, two pairs will be wanted—one for distant vision and one for near work; or even intermediate pairs may be needed, if distinct vision is desired at intermediate distances.

It will be useful here to contrast the diagnosis of M. and H.

In M. distant v is *improved* by a $-v^e$ glass.

In H. distant v is *not made worse* by a $+v^x$ glass.

In M. the retinal vessels move *against* the observer.

In H. the retinal vessels move *with* the observer.

In M. the retinoscopic shadow moves *with* the observer (generally).

In H. the retinoscopic shadow moves *against* the observer.

The amount of M. is the *weakest concave* glass which gives the best attainable distant vision.

The amount of H. is the *strongest convex* glass which gives the best attainable distant vision.

The amount of M. is the *weakest concave* glass with which the fundus can be distinctly seen by the direct method.

The amount of H. is the *strongest convex* glass with which the fundus can be distinctly seen by the direct method.

A few cases are here given to illustrate the method of testing and noting the vision:—

Case 1.—Low M. The patient, a woman, thirty years of age, complains of being near-sighted. On testing the eyes it is found

$$\text{R. E. } v < \frac{6}{60}; \text{ with } -3 \text{ D} = \frac{6}{9};$$

no improvement with cylinders.

J. i. at 30 cm.

$$\text{L. E. } v < \frac{6}{60}; \text{ with } -3.30 \text{ D} = \frac{6}{9};$$

no improvement with cylinders.

J. i. at 30 cm.

Here -3 D was ordered in a *pince-nez* for distant vision; the eyes being used unaided for reading.

Case 2.—High M. The patient, a carpenter, aged thirty-four, complains of not being able to see his work. Examination reveals—

$$\text{R. E. } v < \frac{6}{60}; \text{ with } -9 \text{ D} = \frac{6}{18}.$$

J. i. at 12 cm.

$$\text{L. E. } v < \frac{6}{60}; \text{ with } -9 \text{ D} = \frac{6}{12}.$$

J. i. at 12 cm.

On trial it was found that with -7 D he could read J. i. at a fair distance, and the same glasses gave $v = \frac{6}{24}$. As he was

satisfied with this amount of distant vision, he was ordered only one pair of glasses, -7 D for constant use.

The above form of noting the result of the visual examination will be found a convenient one. Where v at 6 metres does not come up to $\frac{6}{60}$, the patient might be

brought up to the types till he could see the largest—viz. 60, if an exact numerical expression were desired for v ; in most cases it is enough to note that v is less than $\frac{6}{60}$; this is commonly written $v < \frac{6}{60}$.

Case 3.—Low H. Patient, a woman of twenty, complains that she cannot see to work at night.

$$\text{Here R. E. } v = \frac{6}{6}; \text{ with } +2 \text{ D, } v \text{ still} = \frac{6}{6};$$

therefore H. = 2 D.

J. i. 8"—12" (8" the near point, 12" the far point).

$$\text{L. E. } v = \frac{6}{6}; \text{ H.} = 2.50 \text{ D.}$$

J. i. 8"—12".

In this case $+2.50$ worn for work gave complete relief.

Case 4.—High H. The patient, a girl of twelve, was brought with the complaint that she was *short-sighted*. It was found, however, on examination, that it was one of the cases of H. simulating M.; in fact, after atropine, it was found—

R. E. $H = 9 D$; and with $+9 D$, $v = \frac{6}{18}$.

L. E. $= 10 D$; with $+10 D$, $v = \frac{6}{18}$.

She was ordered $+8 D$ for both eyes, an allowance of $1 D$ being then made for the effect of the atropine; these were to be worn constantly. After a few months with the glasses,

R. E. $v = \frac{6}{9}$; L. E. $v = \frac{6}{18}$.

The refracting surface of the eye has hitherto been supposed spherical, so that the image of external point on the retina was either a point or a circle of diffusion; there are, however, many eyes in which the surface is not spherical, so that different meridians of this surface have different curvatures.

This condition of the eye is called **ASTIGMATISM**. It is divided into regular and irregular.

The *irregular* is generally due to some disease of the cornea, which has so distorted it that it is no longer any definite mathematical surface at all. It is seldom susceptible of any optical help, and will not be further alluded to here.

In *regular astigmatism* the surface is formed according to definite laws. There is one meridian of greatest curvature; another, at right angles to the first, of least curvature; and the intermediate ones are of intermediate curvature. These meridians are all nearly circular. The meridian of greatest curvature is generally vertical. To save space, it will, in what follows, be supposed that it is always so, and, consequently, that the meridian of least curvature is horizontal. In considering the refraction of rays by an astigmatic surface, we find that the image of an external point is a short horizontal *line* at the conjugate (to the external point) focus of the vertical meridian, and in the neighbourhood of this focus the image is a horizontal *oval*; at the conjugate (to the external point) focus of the horizontal meridian, the image is a short vertical straight line, and in the neighbourhood of this focus a vertical oval; midway between these two foci the image is a circle.

Now, suppose we have a straight line external to the eye; call this AB , and first suppose it to be vertical. Further, let us call the focus of the vertical meridian F_v ; that of the horizontal meridian F_h ; this line may be supposed made up of a series of points, arranged vertically over one another.

At F_v the image of each of these points is a short horizontal straight line, and therefore the image of AB a series of horizontal straight lines, parallel to one another and placed side by side; the image of AB is then a faint, wide vertical stripe.

At F_h , on the contrary, the image of each point of AB is a short vertical straight line, and therefore the image of this external vertical straight line a series of short vertical straight lines which overlap one another; this image, then, is a thin, well-defined vertical line. Now, suppose AB a little inclined to the vertical. Each point of it will, as before, have a short horizontal straight line for image at F_v ; but these lines do not now lie directly over one another, but are arranged like the steps of a steep staircase, and they overlap one another a little; the image of AB at F_v is then a stripe parallel to it, and rather more defined than when it was vertical.

At F_h the series of short vertical straight lines, which are the images of the points of AB , overlap, but not so directly as they did when AB was vertical: the image of AB at F_h is then a stripe parallel to it, and rather less defined than when it was vertical.

Hence, if AB in its new position slightly incline to the vertical, at neither F_v nor F_h is a clear image formed; still less is the image clear at intermediate points between F_v and F_h , where the image is formed by a series of overlapping, horizontal, or vertical ovals, instead of horizontal or vertical straight lines, as at F_v or F_h .

As AB departs more and more from the vertical its image at F_v becomes more distinct, its image at F_h less distinct; until it becomes horizontal, when at F_v there is a perfectly distinct image formed, whilst at F_h the image is very indistinct.

Hence, when the two chief meridians of the eye are vertical and horizontal, of only two external straight lines are clear images formed, and these are the vertical, of which a clear image is formed at F_h , and the horizontal, of which a clear image is formed at F_v . If we now suppose the retina of the eye situated at F_h , only vertical lines will be seen quite distinctly: other lines will be seen with increasing indistinctness the more they depart from verticality, and horizontal lines will be the most indistinct of all.

If the retina be at F_v , just the reverse of this will be the case—i.e. horizontal lines only will be seen distinctly, others with varying indistinctness; whilst if the retina

be situated neither at F_h nor F_v , no lines will be seen distinctly.

Now, the human eye has the power, by means of its accommodation, of making the position of the retina coincide with either F_v or F_h , or occupy intermediate positions. Hence, generally an astigmatic eye can see distinctly lines parallel to its two chief meridians; not simultaneously, however, but by two different efforts of its accommodative power. But it has no power of seeing distinctly lines in other directions. As the contours of objects are made up generally of lines running in an infinite number of directions, it is easily imagined how indistinctly such objects are seen by an astigmatic eye.

At any given moment, the eye sees distinctly only the outlines of an object parallel to a certain line; by an effort of its ciliary muscle it can so alter its refractive power as to see the outlines running in a direction perpendicular to the first. Probably, an astigmatic eye is thus continually altering its accommodative tension, so as to get clear outlines in two directions of each object that is successively presented to it. This continual change of strain of the ciliary muscle accounts for much of the fatigue from which such eyes suffer.

Regular astigmatism is divided into five varieties; (1) if, A. being relaxed, both chief meridians are myopic—it is called compound myopic astigmatism; (2) if one meridian be myopic, the other emmetropic—it is called simple myopic astigmatism; (3) if one meridian be emmetropic, the other hypermetropic—it is called simple hypermetropic astigmatism; (4) if both meridians be hypermetropic—it is called compound hypermetropic astigmatism; and (5) if one meridian be hypermetropic and the other myopic—it is called mixed astigmatism.

Etiology.—Regular astigmatism is nearly always congenital. After operations on the cornea, however, a considerable amount of regular astigmatism is often seen. It is generally nearly equal in amount and symmetrical in the two eyes. High degrees of M. or H. are nearly always complicated with astigmatism. It often runs in families.

Cylindrical Lenses.—The difference in curvature between the two chief meridians may be corrected by a cylindrical glass. This has no curvature—is plane parallel to its long axis; in the meridian perpendicular to this may be ground to any curvature; whilst the intermediate meridians have intermediate curvatures. The correction of the accompanying M. or H. is of

course made by a spherical glass, on which the cylinder can be ground. Generally, the sphere is given which corrects the meridian of greatest curvature in H., or least curvature in M.; this accordingly must be combined with a negative cylinder, strong enough to correct the other meridian. A cylindrical lens has no refractive effect in a meridian parallel to its axis, and this accordingly in the correcting glass, if a negative cylinder be used, must be placed parallel to the meridian of greatest curvature in H. or of least curvature in M. Suppose, for example, in vertical meridian M. = 6 D, in horizontal meridian M. = 4 D; then a $-ve$ sphere = 4 D would be given, combined with a $-ve$ cylinder = 2 D, with its axis horizontal.

It would come to the same thing if a $-$ sphere = 6 D and a $+ve$ cylinder = 2 D, with its axis vertical were given.

Diagnosis and Measurement.—The complaint is generally of 'weakness of the eyes,' so that at first we do not know that it is not a case of simple M. or H. When, however, with the best spherical glass v is

considerably below the standard $\frac{6}{6}$, astig-

matism may be suspected. This is especially so in the case of H., where degenerative changes in the fundus are relatively rare. The diagnosis can often be made with great certainty by holding up in front of the eye, already armed with the sphere (+ or -) that gives the best v at 20', a weak $-ve$ cylinder, say, -1 D cyl.

If this be held with its axis parallel to the meridian of least curvature, it will almost certainly improve v. Now this meridian of least curvature is, in most cases, horizontal or nearly so.

We hold this weak cylinder, then, with its axis horizontal, and see if v is improved thereby; if not, we slowly rotate it in front of the eye through a complete half-circle, asking the patient if there is any improvement of v in any position. If not, there is no astigmatism. If there is, the position of the axis that gives the best v is the meridian of least curvature of the eye, and the other chief meridian is of course perpendicular to this. We then hold up stronger $-ve$ cylinders with axis in the same position. The weakest cylinder that gives the best attainable v is the measure of the astigmatism.

In this way many cases can be quickly tested both qualitatively and quantitatively.

There are many other tests for astigmatism, both subjective—i.e. depending on

the answers of the patient like the above, and objective. Of the objective the only one we shall refer to here is RETINOSCOPY. A complete discussion of this method will be found under this heading.

In many cases of astigmatism, a satisfactory result cannot be got without using a mydriatic. This may be either atropine, of which a solution gr. ij. ad f3j. may be used three times a day for three or four days; or homatropine, a solution of the same strength for three or four times. The atropine completely paralyses the ciliary muscle, and so makes near vision (except in certain grades of M.) very dim. This effect passes off in about a week or ten days. The homatropine does not suspend the accommodation so completely as atropine; but the effect passes off much more completely than that of the other drug; generally, accommodative power is fully restored in twenty-four hours. It may be used as a substitute for atropine, when the patient cannot submit to the week's dimness of sight the latter generally causes.

The vision is to be tested whilst the eyes are fully under the influence of the drug; an interval is then to be allowed for them to recover (say ten days for atropine, two days for homatropine), and then the glasses ordered which give the best v in this condition. These will generally be found to differ from the best glasses under atropine in being about 1 D weaker, this being the usual amount of the tonic spasm of A. before referred to. If there be a great difference between the refraction with and without atropine, glasses 1 D weaker than those giving the best v under atropine should be given for constant use as soon as the atropine is discontinued. It may be asked, why use atropine at all, if glasses are to be finally ordered adapted to the non-atropinised state? The answer is, partly to provide for these cases of excessive spasm, partly to facilitate the objective examination.

In any case where strong glasses are ordered, either spherical or sphero-cylindrical, the patient must expect a few weeks' discomfort till the eyes get accustomed to working under the new conditions. They should be worn continuously and perseveringly. Children adapt themselves much more readily than adults to such glasses.

A case of astigmatism is subjoined:—

Case 5.—As. The patient, an architect, aged twenty-two, suffers from headache all day. This he attributes to wearing impro-

per glasses. These he has used constantly for the last twelve months; they are R.E. — 6.50 D, L.E. — 5.50 D. Tested R.E. $v < \frac{6}{60}$; with — 7 D sph. \bigcirc — 3 D cyl., axis 80° up and in from vert. $= \frac{6}{9}$. L.E. $v < \frac{6}{60}$; with — 5 D sph. \bigcirc — 2 D cyl., axis 80° up and in from the vertical $= \frac{6}{9}$.

He was ordered these for constant use, and had no further trouble. The symbol used above after sph. (spherical) denotes 'combined with.' The direction of the axis may be indicated as above, or, better still, by a diagram.

Another error of refraction must be referred to. This is ANISOMETROPIA. This term is applied where there is a considerable difference between the refraction of the two eyes. Small differences are common enough in M. and As.; it is only when the difference reaches say 2 or 3 D that anisometropia is spoken of. It is often very difficult to treat if the difference be considerable. In slight cases each eye may be fully corrected, or else the correction adapted to the less ametropic of the two ordered. Sometimes the medium correction answers best; but each case must be treated on its own merits. Occasionally, where one is M., the other Em. or H., the former is habitually used for near work, the latter for distance, and no discomfort felt.

It remains to speak of *spectacles*. The fitting of these may generally be left to the optician; but the surgeon should satisfy himself that the glasses have their centres opposite the patient's pupils, unless it is otherwise desired, and that they are of the strength ordered. To test any given lens, a test glass of its alleged focal power but of opposite denomination—i.e. $+^v$ or $-^v$, according as the lens to be examined is $-^v$ or $+^v$, is held in contact with it, and the two held close to the surgeon's eye and moved rapidly from side to side. If the test glass now exactly neutralise the other, any distant object—say the window-bars—seen through the combined glass remains stationary. If the combination is $+^v$, it moves in the opposite direction, if $-^v$ in the same direction.

Patients often ask if they should have pebbles. These have no optical advantage over crown glass, and are much more expensive. Sometimes reading glasses require to be tilted forward at an angle of 10° or 15° —'angled,' as it is called. This is to be indicated in the prescription. The form a

prescription commonly takes is the following:—

[Patient's name.]

Glasses for reading:

+ 8 D

[Surgeon's name.]

or, in more complicated cases—

[Patient's name.]

Glasses for constant use:

Right eye: + 2 D sph. \bigcirc - 4 D cyl., axis 80°
from vertical up and out.

Left eye: + 2 D sph. \bigcirc - 3.50 D cyl.,
axis 20° from vertical up and out.

[Surgeon's name.]

If any particular form of frame or colour of glass, such as neutral tint, be required, proper directions will have to be added to above. W. CHARNLEY.

REGNOL'S OPERATION. *See* TONGUE, Operations for Removal of the.

RENAL CALCULUS. *See* NEPHROLITHIASIS.

RENAL COLIC is a term employed to describe a train of symptoms, due to the sudden stoppage of the ureter by some foreign body passing down its lumen, or to some morbid condition of its own walls. The onset is nearly always sudden, the most prominent symptom being pain, usually of a very severe kind, due, on the one hand, to the great sensibility of the ureter, and, on the other, to its own efforts to dislodge the intruding mass by virtue of its involuntary vermicular action. The duration of this pain is determined, first, by the accumulation of fluid behind the obstruction, and by the size and shape of the foreign body, and then by the strength of the muscle-fibres of the ureter. Fortunately, it does not usually last long, the mass either being forced onwards into the bladder, or the ureter becoming more or less accustomed to its presence. The causes of obstruction of the ureter, and consequent renal colic, may be the passage of—(1) a calculus, (2) a blood-clot, (3) a caseous shred of tubercular matter, (4) hydatids, (5) a portion of new growth, (6) the presence of a tubercular ulcer in the tube.

The *symptoms* in an ordinary attack are, usually, as follows. An agonising sickening pain sets in, usually with great suddenness, in the renal region, and radiates from this down the track of the ureter into the genitals and inner part of the thigh. With this there is often faintness and even vomiting, the patient probably at the same time breaking out into a cold sweat all over the body. When the first faintness has passed off,

he will probably bend and twist the body nearly double with suffering, and endeavour to relieve himself by contortions in all directions. There will also be, in the male, most likely a retraction of the testicle. In some cases, the temperature is raised, and the pulse becomes rapid and feeble. Then, after a period, usually measured by hours, there is a complete cessation of the pain, as sudden as its onset, and a disappearance of the other troubles as well.

The *diagnosis* is based, first, upon the previous history of the case—i.e. if the patient has passed small calculi or 'gravel' before, or has had attacks of hæmaturia, or evidence of tubercular disease, parasites, or new growth in the kidney. Again, if there has been hæmaturia and the ureter is stopped by blood-clot, the water, previously blood-stained, will be passed clear during the colic, to return to its former red colour with the cessation of the pain, at the same time that small, worm-like clots are passed with the urine *per urethram*. In the same way a small calculus may be passed.

The paroxysms of pain, with which renal colic is most likely to be confounded, are (1) ordinary colic, (2) the passage of biliary calculi, (3) sudden obstruction of the urethra by blood-clots, stone, or new growths. From the first of these it will be distinguished by the seat of the pain and suddenness of the onset, usually after some renal symptom; by the absence of constipation, and then by percussion, which will probably indicate the condition of the intestine. Palpation, too, will often detect the painful spot in the flank where the obstruction of the ureter has taken place, and may even make out the foreign body. From biliary colic a distinction is made by means of the history, the seat of the pain, and in some cases by the occurrence of jaundice. Blood-clots, stone, and new growths in the bladder, leading to sudden obstruction of the urethra, can be demonstrated by the introduction of a catheter or sound, as well as diagnosed from the clinical history.

The *treatment* of renal colic varies with the cause, and resolves itself into palliative and curative. Under the first head will come, rest in the recumbent position, hot belladonna fomentations over the whole side, and the repeated injection of morphia in free doses hypodermically. In the case of blood-clots, calculi, or tissue-shreds, free kneading and manipulation over the track of the ureter, in the hope of assisting the passage of the foreign body into the bladder, may be tried. *See* NEPHROLITHIASIS; NEPHROLITHOTOMY. ARTHUR E. BARKER.

REST.—‘The first and great requisite for the restoration of injured parts is rest,’ was John Hunter’s epoch-making generalisation. Than that, no proposition is more worthy of the surgeon’s thought, none more fertile for his patient’s good. The principle of constitutional and local rest is so interwoven with the whole teaching of this work, that it would be impossible to do it separate justice without time-wasting recapitulation. Yet, as one of those fundamental truths which cannot be inculcated too often or too impressively, an endeavour to methodise some of the most conspicuous advantages of rest may be justified by practical convenience and usefulness.

As movement increases the heart’s action and is opposed to blood-coagulation, so this is favoured, and that retarded, by rest. Hence the value of rest in the treatment of disease and injuries of the blood-vessels, in wounds and aneurisms.

To quote from Mr. Hilton’s classical lectures on ‘Rest and Pain,’ ‘growth and repair have an exact relation to due physiological rest, local and general.’ Accordingly, the repair of solutions of continuity in all tissues, hard and soft, proceeds in closest conformity to the physiological standard and with the minimum risk of pathological complication, the more perfectly divided parts, once re-adjusted, are maintained in a state of absolute repose. On this principle is based the sound practice of infrequent wound-dressing, and of treating broken bones and acute articular affections by immobilising the joints above and below, as well as the seat of mischief.

Mechanical and physiological, constitutional and local, medicinal and manual resources, such as darkness and mental quiet, anæsthetics, opium and allied preparations, position and suspension, cold and pressure, are all, in appropriate proportion, powerfully contributory to rest and repair. Once more experience teaches the great lesson, that complexity in the causation of pathological states necessitates combination of therapeutic resources for purposes of relief and cure.

Rest is something more than a mere negation of motion, as illustrated by the apparently, but not really, simple case of an irritable ulcer on the swollen leg of a big-bellied person. In such a patient, rest in the recumbent posture, and suspension of the foot soon give temporary ease; but recovery is greatly favoured by elastic pressure of the limb, and by administering a brisk purge, which may often be advantageously followed up with opiates. The

constitutional and local rest combine in relieving vascular and nerve tension, and favouring healthy nutrition. In anal fissure and fistula, healing is prevented by the contractility of the very sensitive and active sphincter muscle. Divide as much of it as is necessary to insure rest in the particular case, and healing proceeds painlessly and solidly. The pain occasioned by foreign bodies, such as a thorn in the finger, a fish-bone in the throat, or a stone in the bladder, or by a dislocated or broken bone, ceases with the removal of the cause of unrest, be it extraction of the foreign body or restoration of the displaced part to its normal relations. So with the vomiting and pain due to strangulated hernia. Injuries of the chest and abdomen supply further illustrations in point. In such cases rest in the recumbent posture affords great, but not complete, relief. Where several ribs are broken, with or without wound of the soft parts, the chest requires good padding and abundant bandaging with equable pressure. A lattice-work of millboard, or other mouldable splintage, contributes powerfully to comfort; and so does fixing the arm, to rest the pectoral and dorsal muscles completely, on the injured side. Opium is additionally useful; the medicinal and mechanical treatment combining to reduce the number of respirations, and to favour abdominal breathing, during fixity, rest, and repair of the chest-wall. When the abdomen is bruised or wounded, rest is promoted by sedatives, by resting on the back with the shoulders raised and the thighs flexed, equable pressure being at the same time applied over the abdominal wall. Such pressure may be very beneficially practised, according to the requirements of particular cases, by broad bandages over good padding; or by means of a heavy poultice, or a shot mattress; a sand, water, or ice bag.

In painful cases of retention of urine, when ineffectual attempts have been made to pass a catheter, an anæsthetic may render easy what was before impossible. That failing, opium pushed judiciously to its full action, as indicated by contraction of the pupils, often succeeds in lulling pain, relaxing spasm and congestion, and allowing the urine to dribble, and, by-and-by, to flow. When, in such a case, anæsthetics, the catheter, hot hip-bath, purgatives, and opium all fail, and the bladder can only be saved from threatened rupture by suprapubic aspiration or tapping *per rectum*, urine often flows with comparative freedom *per urethram* once engorgement and spasm of

the passage are relieved by a few hours' rest after the operation. These are only a few illustrations of the value of the great therapeutic principle of rest; the reader interested in its further applications may refer to the articles IMMOBILITY; POSITION; PRESSURE; SUSPENSION; WOUNDS, treatment of

SAMPSON GAMGEE.

RETENTION OF URINE.—When the bladder contains urine which it cannot expel, retention is said to exist.

Causes.—I. *Obstructions.*—(1) Imperforate prepuce. (2) Inflammation of the urethra. (3) Abscess in the prostate, penis, perineum, or about the rectum. (4) Stricture of urethra. (5) Hypertrophy and other tumours of the prostate. (6) Calculus. (7) Tumours of the bladder, of the urethra, and of the penis. (8) Pelvic tumours. (9) Foreign bodies in the urethra, bladder, or rectum.

II. *Direct or Indirect Interference with Nerve-supply of Muscles concerned in Micturition.*—(1) Disease or injury of the cerebro-spinal axis. (2) Hysteria. (3) Drugs. (4) Wounds and contusions of bladder or urethra. (5) Surgical operations in neighbourhood of bladder. (6) Urethral spasm.

Symptoms.—The chief sign is a distended bladder, shown by hypogastric dulness on percussion, or felt by the finger in the bowel or vagina. The patient generally complains of painful and urgent desire to pass water, with constant attacks of straining, called 'spasms.' Sometimes, during a spasm a little urine is passed, giving temporary relief, while frequently the bowel itself and piles, if present, are protruded, and the contents of the rectum evacuated. These urgent symptoms may be more or less absent, sometimes almost entirely so, and the medical man must ever be on his guard, and take care that he does not overlook a chronically distended bladder, for such oversight may lead to disastrous consequences. The cause of the retention will usually be obvious enough; but it is well to remember the following points:—(1) If under fifty years of age, the patient cannot have prostatic hypertrophy. (2) If he is over fifty, and with no history of stricture, the cause is probably prostatic. (3) If under fifty, he may have stricture and never know it, until seized with retention. (4) Should the obstruction be beyond six inches from the meatus, the case is not one of stricture.

Treatment.—Immediate relief is demanded. Usually, the patient is in great pain, and the longer the distended bladder is unrelieved the less likely is it to regain

its entire contractility. A more remote danger is rupture of the urethra or bladder, with extravasation of urine. A hot bath and an opiate may be taken, or a little chloroform inhaled, and perhaps some urine will be expelled; but usually it is well to resort at once to the catheter. To prevent or mitigate the urinary fever which frequently comes on within the first few hours after catheterism, the patient should be at once put to bed after the operation, and if his urine is healthy, an opiate should be administered (liq. opii sed. ℥xv.), and washed down by some warm demulcent drink. The use of catheters in retention of urine may be considered under the following headings:—(1) Nervous retention, (2) inflammatory retention, (3) calculi in urethra, (4) urethral stricture, (5) hypertrophy or other enlargement of the prostate.

(1) *Nervous Retention.*—Here, retention has occurred although the urethra is perfectly healthy. Either the bladder cannot act from temporary or permanent paralysis or from over-distension; or reflex nervous irritation has produced 'spasm' of the urethra, this occurring when retention follows amputation of the thigh or operations for piles or anal fistula. The simplest catheter is one of vulcanised india-rubber, about No. 7 (Eng.); if this cannot be passed, a soft French coudée or olivary catheter may be attempted; if necessary, an English gum or a silver catheter must be used.

Hysterical retention almost always occurs in women. At first, judicious indifference is best; but the case may become serious if altogether neglected. After a safe interval has elapsed, a soft gum or india-rubber catheter should be introduced, and the bladder relieved. If catheterism in any particular case is undesirable, the patient may be placed in a hot hip-bath, and a jug of cold water suddenly thrown over the back, which will often produce the desired effect. See FEMALE CATHETER.

(2) *Inflammatory Retention (Gonorrhœa, Prostatitis, Abscess).*—It is well to try to avoid the use of a catheter. The patient should be put into a very hot sitz-bath and encouraged to pass water while there. If he cannot do so he may be put to bed, and the perineum freely leeches. An anodyne draught may be given if there is much pain. A brisk purge may prove useful. If these remedies fail, then a No. 7 (Eng.) warmed, oiled, soft tapering French olivary catheter may be gently introduced. If this instrument will not pass, a No. 4 or 5 English gum catheter without a stylet may be tried. A silver catheter is rarely necessary, but

when its use has been determined upon, it will be well to administer an anæsthetic, if facilities for doing so are at hand; especially if much difficulty has been encountered, owing to the swelling of the parts or the unruliness of the patient. If the retention is due to prostatic abscess, the passage of the catheter may be followed by a flow of matter, the abscess having ruptured into the prostatic urethra.

(3) *Calculi in Urethra*.—A small English gum catheter can nearly always be inserted between the calculus and the wall of the urethra into the bladder, and the retention relieved. If the calculus is at the neck of the bladder, it may readily be pushed back into the bladder by a large blunt-ended bougie or catheter. If the stone is in the penile urethra, it may generally be easily removed by the long urethral forceps or urethral scoop. See STONE IN THE URETHRA.

(4) *Stricture Retention*.—If, from the symptoms and history of the patient, stricture is suspected, he should be desired to make, if possible, a little water. He may not prove able to make any or more than a few drops; or perhaps a little stream of water will issue. In this case, the size of the stream must be carefully noted. Next, a No. 8 or 9 blunt-ended gum bougie or catheter should be gently passed as far as it will go. This will give a general idea of the situation of the obstruction.

If it is a case of stricture, the instrument will be arrested before it has traversed the first five or six inches of the canal. If the patient has been unable to make water, or can only make it in drops, then the smallest gum elastic catheter must be employed—a No. $\frac{1}{2}$ or No. 1; or, if he has made a small stream of urine, a gum catheter of corresponding size may be selected. The stylet should be removed, the end turned up a little, and a very gentle attempt be made to insinuate the catheter, warmed and oiled, through the stricture. Should the instrument pass fairly into the bladder, the surgeon will learn by the issue of a few drops of water that all is right, and he must tie the instrument securely in. The patient may immediately be able to relieve himself, not only through but by the side of the catheter; for often, in using instruments for the relief of retention from stricture, the mere pressure of the catheter against the face of the stricture will cause urine to flow, and great relief will be afforded. If, however, the stricture is a tight one, urine will not flow outside the instrument; the water may therefore be

allowed to drain drop by drop from the catheter until relief is afforded. If this relief is delayed, and the surgeon is satisfied that the catheter is in the bladder, he need not be in a hurry to remove the instrument. The patient may be soothed by a hot bath or by an opiate draught, and in time the stricture will dilate from the presence of the inlying instrument, and urine will be freely discharged by the side of the catheter.

Should the English gum catheter fail to pass either with or without its stylet, a small French olivary catheter may be attempted. If this is not successful, then a No. 1 silver catheter must be used, the patient standing or lying down from time to time, as the surgeon thinks best. The surgeon's left forefinger in the bowel is often of assistance, and not infrequently the introduction of a catheter will be much facilitated by placing the patient under the influence of an anæsthetic. If a catheter is successfully passed, whether a soft or a silver one, it should be tied in. (For the further treatment of the case, see STRICTURE OF THE URETHRA.) Should the stricture be a very severe one, it will be a great boon to the sufferer if the surgeon can arrange for catheterism to take place in the patient's bedroom, so that, when once the catheter is passed, it can be tied in, and the treatment of the stricture commenced. Otherwise, if the catheter has to be withdrawn, the second catheterism, which is very likely to be soon necessary, may prove more difficult than the first from the swelling and possible laceration of the parts. Supposing catheterism fails, and opiates and hot baths give no permanent relief, the surgeon has the choice of several modes of giving exit to the retained urine. This question will be further discussed at the end of the consideration of prostatic retention.

(5) *Prostatic Retention*.—If the sufferer is over fifty years of age, and without any history of stricture, the cause is probably prostatic. He should stand with his back to the wall; the surgeon should sit down in front of him, and pass a well-oiled No. 7 or 8 (Eng.) vulcanised india-rubber catheter. No skill is required; if it passes, all is well; if it will not pass, it must be removed, and a No. 7 or 8 French coudée catheter tried. The operator should make some mark on this instrument, so that on looking at the proximal end he can always tell, when the bent end is in the urethra, which way the bend is turned. Holding the penis up against the patient's abdomen, and passing the first five inches of the coudée catheter

vertically down the urethra, the surgeon keeps the penis and the catheter strictly in the middle line, and the bend of the instrument always towards the patient. As about the sixth inch is pushed in, he gradually brings the penis and catheter down to the level line, and as the next and succeeding inches of the catheter pass, slowly drops the penis and catheter until they almost point to the patient's toes. As a rule this catheter will ride easily into the bladder. If it does not enter, it is very probable that the point has caught in the prostatic sinus. To disengage the point of the catheter, it is gently withdrawn for about an inch or more, and turned on its long axis so that the bent-up end points laterally to the right or left, instead of upwards as it did before. An attempt is now made to pass it into the bladder; and repeated if unsuccessful, turning the point first to one and then to the other side. Frequently this manoeuvre will prove successful.

If the *coudée* catheter will not go, a very soft-ended olivary catheter may be tried, and, if necessary, a large *coudée* (No. 12); for large instruments, although they give more pain than small ones, will often avoid, by reason of their size, an awkward place which will engage a smaller instrument. When all these instruments fail, a *bicoudée* will sometimes be successful. Here may be mentioned with praise the silk-web *coudée* catheters made in London, and of recent introduction. They are soft and highly polished, and in the writer's hands have passed when the ordinary *coudée* has failed. This is due to their softness, which makes them practically *bicoudée* catheters, and enables them to ride easily over the bar at the neck of the bladder.

If none of these catheters can be passed, the surgeon may take an English gum catheter, No. 8 or 9, and, removing the stylet, may put the catheter into any shape he likes by softening it in hot water, moulding it to his taste, and then making the shape for a time permanent by dipping the catheter into cold water. A very excellent plan is to keep one of these catheters permanently on a stylet which has been over-curved. When required for use the stylet is removed, and the catheter keeps its curve so well in the urethra, that the end will often successfully surmount the obstacle at the neck of the bladder. Another plan of using the English gum catheter, in these difficult prostatic cases, is to introduce it on a stylet. When the catheter becomes engaged at the obstruction, the instrument is held in place with the one hand, while the

other hand withdraws the stylet for an inch or two. This movement causes the end of the catheter to rise and come forward in the prostatic urethra, frequently with the happy result of entrance into the bladder.

If the operator is still unsuccessful, silver catheters must be tried, of various curves (prostatic), with the patient either standing or lying. The introduction of the left forefinger into the bowel will often facilitate the passage of these instruments by pressing the point forwards. In the use of all prostatic instruments, when once a catheter is passed, the patient must be closely watched as the water is drawn off, and the catheter at once plugged or withdrawn, should any signs of syncope arise. Speaking generally, it is unwise to draw off more than twenty ounces at the first catheterism. In all cases the patient should at once be put to bed, and for four or five days be kept warm and comfortable in the horizontal position. He must be carefully watched for a recurrence of retention, which will be sufficiently obvious. The great danger, however, consists in the patient after a few hours making some water naturally, without by any means emptying his bladder. This deceives the unwary surgeon, and the bladder is allowed to continue partially emptying itself until obstinate and even dangerous cystitis is set up. Within at least twelve hours from the first retention, with very rare exceptions, the catheter should be passed again immediately after the patient has made water, and the amount of water not passed naturally carefully noted. This amount will determine the future treatment. *See PROSTATIC HYPERTROPHY.*

In cases of difficult prostatic catheterism, the question will often arise after the bladder has been emptied—Shall the catheter be tied in or taken out? If the difficulty has been very great, and if the catheter introduced is a soft one, it may certainly be tied in, its orifice securely plugged, and the urine drawn off when necessary. Usually, such a catheter will require changing in four or five days, and it will be well to keep the interior of the bladder free from decomposing urine, by daily injections through the catheter of a warm solution of boracic acid (3 to 4 drachms of the saturated solution to four ounces of water), or of carbolic acid (℥ij. to fʒiv.). Such a proceeding is justifiable if great difficulty has been experienced, and if the urethra has been much injured; and it is occasionally justifiable in ordinary cases, if the surgeon cannot frequently visit his patient. Here, however, it may be said that, when a man has had prostatic retention

of urine his life hangs in the balance, and whether the balance goes up or down largely depends on the care his surgeon can give him, the most essential part of this care being immediate and easy catheterism directly the bladder cries out for relief. Unless under absolute necessity, a silver catheter must not be tied in. A soft catheter may usually be safely retained—and stress may be laid upon this, as formerly it was taught that a catheter should never be tied in in cases of enlarged prostate. If the retention has with great difficulty been relieved by a silver catheter, and if it is desirable to tie a catheter in, the retention of the metal instrument may be avoided by placing a soft catheter on a stylet, bending it to exactly the same shape as the silver catheter, and passing it directly the silver one is withdrawn.

With patience, gentleness, and skill, the surgeon should always succeed in passing a catheter in a case of prostatic retention. But supposing that from great irregularity of the passage, want of suitable instruments, or in consequence of injury inflicted during previous attempts at catheterism, no instrument can be introduced, what is the surgeon to do? In the first place, for obvious reasons the relief must be immediate; any delay is absolutely wrong; and in the second place the relief must be obtained by the simplest means. The simplest means of evacuating a distended bladder is, undoubtedly, by suprapubic aspiration. Afterwards, with rest and after a thorough evacuation of the bowels, a catheter may often easily be passed into the bladder through the urethra. Should retention, however, recur, and catheterism again fail, a second or even a third aspiration is permissible. But, although the bladder has been safely aspirated many times (ten or twelve), fatal extravasation and abscess have been known to follow a second aspiration, and the surgeon is advised not to aspirate the bladder more than two or three times. Afterwards, if a catheter cannot be passed, suprapubic puncture with trocar and canula is recommended.

There are other methods of puncturing the bladder, notably the rectal one, which still has advocates. These methods are all described under **BLADDER**, Puncture of the. See also **BOUTONNIÈRE**, the Operation of.

G. BUCKSTON BROWNE.

RETINA, Affections of the.—**CONGENITAL ABNORMALITY**.—Occasionally, the nerve-fibres regain, at the edge of the papilla, their medullary sheath which had been previously lost at the lamina cribrosa,

and we have the condition known as 'opaque nerve-fibres.' The papilla itself often escapes, but sometimes its periphery, and, very rarely, even its entire surface, with the exception of the physiological cup, may be involved and appear white in consequence. The condition usually occurs in the form of a brilliantly white patch, narrower at the end next the papilla, with which it is nearly always continuous. Its broader peripheral end has a ceased-out, brush-like appearance, from the separation of the fibres. The affected area is generally at the upper or lower edge of the disc, and the large blood-vessels there present are more or less concealed by it. Exceptionally, it extends all round the disc, and, still more rarely, the patch may be detached from the disc altogether. We get a scotoma corresponding to the extent of the opaque area.

DISEASES.—With the exception of its blood-vessels and its pigment-epithelium, the retina is almost perfectly transparent, and therefore practically invisible ophthalmoscopically. Its diseased conditions then may be recognised by a loss of its transparency, or by changes in its circulation or in its pigment layer.

CHANGES IN THE SIZE, COURSE, AND STRUCTURE OF THE BLOOD-VESSELS.—First, we will consider shortly disturbances of the retinal circulation, as evidenced by changes in the size and course of the vessels and in the structure of their walls.

In judging of the *size* of the retinal vessels we regard chiefly the larger branches on the optic disc, comparing them with the mental impression of those of an average normal eye. Slight departures from the normal may readily be overlooked by such a method, and the observer must be careful to note the number of the branches of artery or vein on the disc, as, the smaller the number of these, the larger each one will be in proportion in the healthy fundus. Again, by the direct method of observation, the vessels will appear larger in the myopic and smaller in the hypermetropic eye, while by the indirect method the opposite effect will be produced (**OPHTHALMOSCOPY**). It is important to observe any change in the relative size of arteries and veins, the diameter of the normal artery being from two-thirds to three-fourths that of the corresponding vein.

A congenital general enlargement of the retinal vessels, containing unusually dark blood, is met with in congenital defects of the heart with cyanosis. A temporary distension of the retinal vessels exists in active hyperæmia, as from vaso-

motor influence in exophthalmic goitre, local overfilling from obstruction in another arterial region, &c. A general reduction in the size of the vessels is sometimes found in general anæmia and in Bright's disease, or it may be due to local pressure on the central artery. The arteries alone may be small in cases of neuritis and of embolism, and occasionally in general anæmia, where the veins appear large from being flattened, owing to their reduced intravascular tension. In true venous distension we find these vessels large, rounded, abnormally dark, and tortuous. This condition of venous distension may be dependent on local or general causes. Locally, it may be due to neuritis, or thrombosis of the central vein, and is found sometimes in glaucoma and in cases of rapidly occurring pressure on the cavernous sinus. The retinal veins may be congested, as part of a general venous congestion in the head from pressure on the jugular or innominate veins. Again, the retinal congestion may be part of a general congestion, the latter being either *acute*, as from coughing or any effort, or *chronic*, as in mitral disease and emphysema of the lungs. An irregular dilatation or varicosity of the veins is sometimes observed in aged persons and in glaucoma.

A *tortuous course* is characteristic of congested veins, but it has exceptionally been found with normally sized vessels in healthy eyes. An antero-posterior curve in the vessels may be caused either by swelling or detachment of the retina, and is recognised mainly by loss of the central light-streak.

Visible pulsation in one or more of the large veins on the disc is not uncommon in the normal condition, and is best seen just at the edge of the physiological cup. It also occurs, pathologically, from the same causes that produce arterial pulsation. This latter is never normally present, but occurs in acute anæmia, in aortic regurgitation, and in increased intra-ocular tension, whether from disease or mechanically produced by finger-pressure from without. It is usually visible only in the vessels on the disc itself, but in aortic cases it may be traced peripherally to branches of comparatively small size.

Changes in the vascular walls are sometimes recognisable by the ophthalmoscope, a distinct white line bounding each side of the red blood-column. This appearance may be due to thickening of the middle or outer coat of the arteries, or to an accumulation of leucocytes in the peri-vas-

cular sheath. Aneurisms may occur either on the primary branches of the central artery, or on the smaller twigs and capillaries of the retina. They are of clinical importance from their being usually associated with a similar condition of the small vessels in the brain and elsewhere.

Apart from circulatory changes, we may diagnose retinal affections by an interference with its normal transparency. Thus, we may have diffuse haze from oedema, red patches from hæmorrhages, black opacities from deposits of pigment, or opaque white areas from exudation or fatty changes. Again, it and its vessels may be elevated in part of the fundus as the result of an exudation or solid growth beneath.

HÆMORRHAGES may occur in the retina at any part of the fundus, and are readily recognised, when recent, from their bright red colour. There may be only one or two, or they may be practically countless; and they may be of any size, from a barely visible spot or streak to a patch much larger than the optic disc. Occasionally, a single, large, round or oval, sharply defined hæmorrhage occurs at the yellow spot. Hæmorrhages are most commonly found in the neighbourhood of large vessels in the nerve-fibre layer, and then present a striated or 'flame-shaped' appearance, from the extravasated blood lying between the nerve-fibres. Not infrequently they occur in the inner nuclear layer from the fine capillary networks found in this position, and they are then round or irregular in form. If large, they may either burst into the vitreous or cause detachment of the retina. They interfere with sight according to their size and position; those at the yellow spot causing necessarily a large central scotoma. They become darker in colour with time, and absorption takes place gradually, its rapidity being greatest in hæmorrhages of small size and in those not associated with disease of the vessels. Ultimately no trace may be left, or there may be dark pigmentation or again yellowish-white spots.

Causes.—We may meet with them as part of an inflammation of the retina or optic nerve, but more frequently they are dependent directly on general conditions, or on retinal disease consequent on general conditions. The extravasation may be due to rupture of vessels or to diapedesis. The following statement will serve to show the manner of their occurrence.

A. Rupture of vessels from—

1. Increased intravascular pressure, local or general. (a) *Local*—e.g. from contusion of eyeball, venous thrombosis, optic

neuritis with much constriction of veins, and all forms of retinitis. (b) *General*—as from hypertrophy of the left ventricle, cough or other violent effort, stoppage of habitual discharges, the high arterial tension associated with gout, &c.

2. Rupture from sudden diminution of the vitreous support, as in wound of the globe and in iridectomy for glaucoma.

3. From weakness of a degenerated vascular wall, as in sclerosis, fatty degeneration, or miliary aneurisms of the retinal vessels; sometimes associated with embolism or thrombosis of the small arteries. The vascular change may be a simple senile condition, or may be a concomitant of a general affection such as Bright's disease.

B. Diapedesis may be the result of—

1. Increased intravascular pressure, or

2. An altered condition of the blood.

This latter is probably responsible for the hæmorrhages found in cases of diabetes, severe anæmia, leucocythæmia, ague, purpura, scurvy, and pyæmia. Retinal hæmorrhages are occasionally met with in young people without any obvious cause. Such cases are probably due to increased intravascular tension and altered conditions of the blood. They are commonly found in association with the hæmorrhagic diathesis.

The *treatment* of hæmorrhage of the retina must necessarily vary with the general and local states with which it is associated or on which it depends. In recent cases iced compresses may be applied to the lids.

INFLAMMATION OF THE RETINA is usually the result of some general disease, and the classification of its forms commonly adopted is clinical rather than pathological. When the inflammation commences in the retina the papilla is generally secondarily involved, and, again, retinitis—mainly of the inner layers, is not infrequent in cases of papillitis. The principal ophthalmoscopic evidences of retinitis are loss of retinal transparency, dilatation of the veins, and a tendency to the occurrence of hæmorrhages and white patches. Anatomically, we find serous infiltration of the retina, swelling of the Müllerian fibres, fatty degenerations, inflammatory exudations, hæmorrhages in the inner or middle layers, and hypertrophy and sclerosis of nerve-fibres. Sometimes there are numerous opacities in the vitreous. The impairment of vision, both temporary and permanent, varies much in different cases.

The *treatment* must be regulated mainly by the general condition of the patient. All strong light should be cut off from the eyes

by wearing dark neutral-tint glasses, and complete rest be ordered. Counter-irritants or leeches to the temples may be advisable.

HÆMORRHAGIC RETINITIS is the term applied to cases where we have numerous hæmorrhages along with evidence of retinal inflammation, occurring in association with disease or disorders of the circulatory system. It usually affects one eye only. The hæmorrhages are small and numerous, and are found widely distributed over the fundus, chiefly in the inner layers of the retina. The papilla is hyperæmic, with blurred margins; there is a slight diffuse opacity of the retina, and its veins are dark and swollen. Occasionally, we find a few circumscribed white spots in the inner retinal layers, probably due to fatty degeneration or to aggregation of leucocytes.

Causes.—This disease is found in connection with diseased cardiac valves, hypertrophy of the left ventricle, aneurism of the great vessels, and with arterial sclerosis. It also sometimes occurs on sudden suppression of the catamenia at the climacteric period. The manner of its production is obscure. It may perhaps be explained by chemical changes in the blood, or by multiple embolism of the small twigs of the central retinal artery. There are usually permanent changes left in the retina and papilla.

The *treatment* must be general; iodide of potassium may be used with apparent advantage.

ALBUMINURIC RETINITIS is characterised by the presence of numerous light-coloured patches, and of minute, opaque, very white dots or striæ at the yellow spot. The affection of the papilla varies between slight passive congestion and great engorgement; in the latter case there is a marked tendency to hæmorrhages, which occur principally in the nerve-fibre layer. The soft-edged light-coloured patches occur early, and are found mainly in an annular zone surrounding the papilla. The white punctate spots appear later, and are arranged in the form of a star or asterisk, with its centre at the fovea centralis. Both eyes are practically always affected. The large light patches are usually behind the retinal vessels, and are due to a deposit of fatty granules in the nuclear and internuclear layers. When superficial to the vessels, the opacity is caused by a local hypertrophy of the nerve-fibres. The white dots at the macula are due to a fatty degeneration of the inner ends of the Müllerian fibres.

Causes.—This retinitis is most commonly associated with chronic disease of the kidney, especially the contracting form, but it

is also frequently found in the albuminuria of pregnancy and not uncommonly in acute nephritis after scarlatina. It has been observed in about 13 per cent. of all cases of albuminuria. The occurrence of the ocular changes is probably to be explained by the altered condition of the blood, arising from retention of products that ought to be eliminated and from the hydremia produced by the loss of albumen. We may have a papillitis or a papillo-retinitis, in connection with albuminuria, without the typical appearance above described. On the other hand, retinitis quite of the albuminuric type occurs exceptionally in connection with intracranial affections, cardiac disease, diabetes or anæmia, without there being any evidence of renal disease.

If improvement takes place in the renal affection the retinal changes may subside, but the star-shaped grouping at the macula lasts for a long time. We often ultimately get optic atrophy, narrowed vessels with double white lines, and disturbances in the retinal pigment. Sometimes, we get a restoration of perfect vision with a normal fundus, as in the cases associated with pregnancy.

SYPHILITIC RETINITIS.—This is an inflammation of a chronic diffuse type without gross ophthalmoscopic changes. The larger veins are somewhat distended and dark, and the outline of the papilla is blurred. The retina itself becomes hazy, especially in the neighbourhood of the papilla and along the larger vessels. White patches and hæmorrhages are rare. Very commonly there are numerous dust-like opacities in the vitreous. It generally occurs secondarily to choroiditis, but may exist alone, and either in one or both eyes. It usually comes on late in the secondary stage, about the end of the first year or later, and is most common in subjects of mature or advanced age. It has been also met with in the congenital form of the disease.

Symptoms and Course.—There is considerable failure of vision, sometimes micropsia, and always marked night-blindness. It lasts for months, but the result is generally favourable, the retina recovering its transparency and the other changes disappearing.

The *treatment* must be energetically anti-syphilitic, mercury being the remedy chiefly to be relied on.

RETINAL DISEASE IN LEUCOCYTHÆMIA occurs in about one-third of the cases of the splenic form. It is always bilateral, but often unequal in degree in the two eyes. In a typical case, we find prominent white

patches surrounded by a hæmorrhagic border: these are met with at the limits of the retinal circulation—viz. in the centre, and quite at the periphery of the fundus. The general fundus-reflex is of a bright orange-yellow colour; the retinal arteries are bright orange and the veins light carmine. The usual signs of retinitis are also present, such as blurring of the edges of the disc, slight opacity of the retina, and occasionally small hæmorrhages and white spots.

RETINAL DISEASE IN DIABETES occurs comparatively rarely, but is always bilateral. Usually we simply find retinal hæmorrhages in this association, but, in severe, long-continued cases, retinitis may occur with appearances much like what we find in albuminuria. In the diabetic form, however, the whitish patches are generally smaller, and there are very frequently opacities in the vitreous. Vision is necessarily much reduced in all severe cases, and the prognosis is unfavourable.

CENTRAL RETINITIS FROM EXPOSURE TO DIRECT SUNLIGHT has been met with in several cases after observation of an eclipse. Immediately after the exposure there is more or less loss of central vision, in the form of a positive scotoma. In severe cases this persists, though generally some improvement takes place. Ophthalmoscopically, the macula is found to be more darkly pigmented than usual, and the position of the fovea is occupied by a greyish-yellow spot. It is probable that the pathological changes consist in proliferation of the pigment-epithelium, and exudation between it and the chorio-capillaris. In severe cases with persistent scotoma, there is possibly also destruction of the outer segments of the rod and cone layer.

The *treatment* consists mainly in the use of dark glasses, and leeches or counter-irritants to the temple. Later, strychnine and galvanism have been recommended.

RETINITIS PIGMENTOSA is a term in common use to designate a disease where a certain group of symptoms and definite course are usually found in association with pigmentary changes in the retina. The disease is symmetrical and chronic, usually beginning in early life, and often terminating in blindness soon after middle age. Night-blindness is the earliest and most characteristic symptom. There is next loss of visual field, generally at first in the form of an annular scotoma, but the periphery soon also fails, and a small central field alone remains. Central vision may remain good for a long time. The

affection is often found in several members of the same family, and such patients are not infrequently defective in intellect. It is believed by some that consanguinity of parents may produce it.

Ophthalmoscopic examination shows a yellowish-red waxy atrophy of the optic disc; marked diminution in size of the retinal vessels, especially the arteries; and much pigment in the retina, largely in its inner layers, where black masses, shaped somewhat like bone-corpuscles, lie superficial to the retinal blood-vessels. This pigmentary deposit is found chiefly in a belt situated midway between the centre and the periphery of the fundus, and thinning out at each edge. There is no hyperæmia at any period of the disease. No constant relation exists between the amount of pigment or other ophthalmoscopic change and the loss of sight; indeed, we may have the usual symptoms and course of the disease without the presence of any abnormal pigment in the retina. Similar changes in the retina and optic nerve are found, not infrequently, secondary to choroidal inflammation, but in such cases we have the atrophic changes in the choroid in addition. Ophthalmoscopically considered, pigmentary degeneration of the retina is essentially the same from whatever cause it may arise. But the term *retinitis pigmentosa* has been chiefly used as a clinical designation, and as denoting the group of symptoms, course, and ophthalmoscopic appearances of, practically, the only form of pigmentary degeneration which can occur without retinitis; while the symptoms and course of this disease may be present without the usually associated pigmentary degeneration. The condition is in reality a chronic sclerosis, occurring either as a primary disease or secondary to intra-ocular inflammation, and generally, but not always, associated with a pigmentary degeneration of the retina. Pathological examination of the retina shows an increase of the connective-tissue framework, atrophy of the nervous elements, and thickening of the walls of the vessels.

The pigmentary changes are partly atrophic in nature, but mainly consist in an infiltration of the retina with newly formed pigment aggregations. These latter follow the course of the vessels, and are found most conspicuously at their branchings.

Galvanism is the only form of *treatment* of any avail in this affection, sometimes causing a marked improvement both in field and in central acuity. It ought to be employed as described previously (*see* OPTIC NERVE, Atrophy of), and if it prove ser-

viceable, should be persevered with, as otherwise the improvement cannot be expected to last long.

THROMBOSIS may occur in the central artery, but it is rare, and indistinguishable during life from embolism. Occasionally, thrombosis affects the central vein behind the eyeball or one of its large branches on the fundus, and usually leads to deterioration of vision and marked ophthalmoscopic appearances. The sight fails suddenly, and more or less completely according to the extent of the closure and the size of the vessel affected, but generally it soon improves again somewhat. In a marked case, the veins of the retina are found to be tortuous and enormously distended, the arteries often small, and both sets of vessels near the disc are concealed in great measure by large opaque, white, diffuse masses of exudation and by numerous hæmorrhages. The latter are of all sizes here, and smaller ones extend well out to the periphery of the fundus. The yellow spot region is of a light clay-colour, with the fovea centralis conspicuous as a very minute cherry-red spot. The papilla looks normal, with the exception of slight blurring of its margins. The affection occurs principally in the aged, often with a family history of gout, and nearly always in only one eye.

EMBOLISM may occur in the central artery itself or in one of its branches, and may be either complete or partial. It is seldom bilateral, and is more common on the left than the right side. Embolism in other vessels always co-exists, the usual cause being heart-disease, especially mitral. It may be found in association with atheroma of the aorta, pregnancy, and Bright's disease, and may consequently occur at any age. In complete embolism the plug is generally near the lamina cribrosa, and the leading symptom is sudden blindness of one eye. There is frequently a temporary improvement a few hours after its occurrence, from the establishment of an imperfect collateral circulation, but the usual final result is absolute blindness. In plugging of a branch, the visual defect is usually partial from the first, the final result likewise being loss of vision corresponding to the distribution of the affected vessel.

Ophthalmoscopic Appearances.—The optic disc is pale, with somewhat blurred edges. There is a diffuse, misty opacity of the retina from œdema, best marked in the yellow spot neighbourhood. Corresponding to the fovea centralis is a bright red spot, where the normal choroidal reflex shines through the outer layers of the retina, and

appears specially red by contrast with the surrounding cloudiness. The large vessels are usually small near the disc, the arteries being often reduced to mere white threads or to narrow red blood-columns bounded by opaque white lines. Within the first day after the occurrence of an incomplete blocking of the vessel, the blood may be seen both in the arteries and veins in the form of short detached columns. This appearance is most common in the arteries, where the short columns may be observed to move forward in a jerky fashion. Increased tension from finger-pressure cannot produce visible pulsation in the vessels. Small hæmorrhages often occur near the optic disc. After some days the pulsation on pressure returns in all the blood-containing vessels, the retinal œdema slowly disappears and the disc gradually becomes atrophic. Where a branch only is affected, changes similar to the above are found in its area of distribution.

As regards *treatment*, massage of the eyeball has proved beneficial in several cases, and should be tried. It is probably best effected by alternate, prolonged, moderately firm pressure on the globe and sudden removal of this pressure.

DETACHMENT OF THE RETINA.—In this condition the retina proper is separated from its pigment epithelium, and a serous fluid usually occupies the interval. Except at the fovea centralis and ora serrata, the retina is naturally very loosely attached to its epithelium; and fluid once present between them readily gravitates downwards to the lower part of the fundus, where old standing detachments are most commonly found. Occasionally, the displacing agent is an extravasation of blood, or a solid plastic exudation from choroiditis, or a choroidal tumour pushing the retina forward. Sub-retinal fluid may be effused, primarily, either as a hæmorrhage or as a serous exudation in connection with inflammation or tumour of the choroid. The common reason of detachment, however, is probably some alteration in the vitreous—either a mere diminution of its support to the retina, or contraction of connective-tissue formations within it forcibly dragging the retina away from its normal position. In such cases the sub-retinal effusion of fluid is secondary.

One of the most common *causes* of retinal detachment is progressive myopia, where we have both choroidal inflammation and alterations in the vitreous. Perforating wounds of the sclerotic may lead to detachment, either immediately, from a loss of vitreous, or subsequently, from contraction

of the cicatricial tissue at the seat of puncture. In many cases no cause can be discovered.

Anatomically, the detached retina undergoes a gradual degeneration, the nervous elements being destroyed and its connective tissue hypertrophied.

Ophthalmoscopic Appearances.—On illuminating the patient's eye with the ophthalmoscopic mirror held at twelve to eighteen inches distance, we observe a want of uniformity in the reflex obtained, a greater or lesser extent of the fundus appearing bluish-grey or whitish in contrast to the normal red seen elsewhere. This discoloured portion is usually folded and more or less tremulous, and corresponds to the detachment; on its surface we see the retinal vessels as slender, dark, stiff-looking tortuous lines. In a recent shallow detachment we find no such difference in colour, but its vessels have the characters just mentioned, though they stand out less conspicuously, from the absence of the strong contrast furnished by a light-coloured surface. By careful measurement of the refraction of the vessels, on the affected and unaffected areas of the retina, we can estimate the depth of the detachment, and in difficult cases determine whether really a displacement exists. Having satisfied ourselves of the presence of a detachment, we should note its extent and the character of its boundaries, its mobility on movements of the eye, its colour, its depth, and the degree of folding. We are thus in a position to decide as to the probable nature of the displacing agent. Not infrequently, floating opacities in the vitreous, changes in the lens, or iritic adhesions are present and interfere with our examination; under such circumstances the indirect method of observation is particularly valuable. The grey colour of a detachment is due to the opacity of the retina; the darkness of the blood-vessels is due partly to loss of the central light-streak, partly to contrast, but mainly to the fact that they are principally seen here by *transmitted* light, the greater part of which is absorbed by the blood-column.

Symptoms.—There is frequently a history of sudden impairment of vision, objects appearing distorted or as if covered by a thick black veil. Sometimes we have complaints of flashes of light and of red or blue colour-sensations. Light is diminished in the part of the field corresponding to the detachment. Central vision may remain good for some time if the macula has escaped; but, in the majority of cases, the detachment extends gradually, and the sight

becomes progressively worse until, ultimately, there is complete blindness or only the barest perception of light.

Treatment.—In recent cases we can often get satisfactory improvement of vision for a time at least, though the measures most successful are decidedly irksome. Rest in a dimly-lighted room is particularly to be recommended, the patient lying on his back on a bed or couch, and the affected eye kept covered with a pressure-bandage. All exertion or sudden effort must be avoided, and the bowels are to be carefully regulated. Puncture of the sclerotic at the site of the displaced retina, so as to permit of the escape of the sub-retinal fluid, is, possibly, a judicious preliminary to the above method of treatment. Repeated sub-cutaneous injections of pilocarpine have also been used and approved of by many, but their employment is not without risk, and the advantage problematical. Neither puncture nor pilocarpine ever does much good without rest, and it is extremely doubtful whether the latter alone does not give results as satisfactory as any.

GLIOMA OF THE RETINA is essentially a disease of early life. It commences insidiously without inflammation, grows rapidly, and, if left to itself, soon leads to the death of the child. By its growth forwards it soon fills the eyeball, perforates the sclerotic or corneal margin, and involves the other orbital structures, so that, finally, we get the appearance of an enormous red fleshy protrusion without any visible trace of the globe itself. In its extension backwards it travels along the optic nerve, and ultimately involves the brain—not infrequently it causes secondary deposits in the scalp, brain, the neighbouring lymphatic glands, and occasionally in the liver and other distant parts. Rarely it attacks both eyes independently. It has occasionally been met with in several members of the same family.

Diagnosis.—In as far as its onset is painless and unaccompanied by inflammation, the attention of the parents is generally first aroused by seeing a whitish reflex from behind the pupil. The vision is commonly very early affected, while the eye still looks natural and the tension remains normal. By the time the whitish reflex is observed, however, there are often signs of secondary glaucoma, increased intra-ocular tension, dilatation of the pupil, and engorgement of the scleral veins, while the eye is now sometimes tender. By focal illumination we see a yellowish-white, rounded or lobulated, solid-looking mass in the vitreous,

with blood-vessels and often small hæmorrhages on its surface. The vessels are easily distinguished from those found on a detached retina by their irregular distribution, different mode of branching, greater breadth, and somewhat brighter red colour.

Pathology.—Its naked-eye appearance is that of a soft, marrow-like growth, of a whitish or reddish-white colour, sometimes studded with small, white, chalky-looking dots. The formation originates in the neuroglia of the retina, usually in that of the inner granular layer. We find here deposits of small roundish cells, closely packed together in a structureless, finely granular interstitial substance. Later on, as the tumour grows, we find large groups of spindle-shaped cells and fibrillated bands (gliosarcoma), and occasionally evidences of fatty and calcareous degenerations.

The *treatment* consists in early removal of the affected eyeball, along with as much nerve as we can conveniently get at. If the other orbital contents are affected while the nerve at the point of section appears healthy, it is advisable to thoroughly clean out the orbit and then destroy the surface with chloride of zinc paste. If the tumour has attained a large size, its removal cannot be expected to save life, and it is often advisable in these circumstances to leave it alone. In such a case, the child's health must be kept up as well as possible, and opiates given, if necessary, to relieve pain and induce sleep. R. MARCUS GUNN.

RETINOSCOPY (Keratotomy).—(In this article the following abbreviations are used:—M. = myopia or myopic, H. = hypermetropia, As. = astigmatism, E. = emmetropia, D. = dioptré, v = vision.)—Retinoscopy is a method of determining by the ophthalmoscope the nature and extent of anomalies of refraction of the eye. It depends on the following optical facts. Supposing a patient, with artificially dilated pupil, seated in the ordinary position for ophthalmoscopic examination, and that we place ourselves at about forty-eight inches from him and reflect the light from a well-defined gas-flame into his eye, by means of a *concave* perforated mirror of about nine inches focal length. If we then look through the perforation in the mirror, we see the ordinary fundus-reflex. Now, if we give the mirror slight rotations about its vertical axis, so that it faces in different directions, still remaining in front of our eye, we then see something that has the appearance of a shadow with a vertical edge, moving horizontally across the illuminated area of the

patient's pupil, either in the same direction as the mirror changes face or in exactly the opposite direction. If, for instance, we turn the mirror to our right, the shadow moves horizontally, either to the right or to the left. Now, if it moves to the right—i.e. in the direction in which the mirror changes face—the patient's eye is M.; if it moves to the left—i.e. in the opposite direction to that in which the mirror changes face—the eye is (generally) H.; if no distinct shadow-movement is seen at all, the eye is E. (nearly).

The observation just described is the germ of retinoscopy. It is convenient to use the terms 'with' and 'against' in describing the movement of the shadow with reference to that of the mirror; for the future, then, we shall speak of the shadow moving 'with' or 'against' the mirror, according as it moves in the same or opposite direction to the change of face of the mirror.

It may be shown that this so-called shadow is really the edge of the image of the gas-flame, formed by one reflection at the mirror and two refractions through the patient's eye, and further, that the change from movement 'with' to movement 'against' takes place, not where the patient's eye is exactly E., but where it is M. about 1.0 D; but as this does not differ much from E. we may say roughly that in M. the shadow moves 'with' the mirror, in H. 'against' the mirror, and that in E. no distinct shadow is seen at all. We have supposed that the mirror is rotated round its vertical axis; this, however, is not at all essential; any axis will do, but perhaps the vertical or horizontal is most convenient. Further on, when we come to treat of As., we shall have to suppose rotations round various axes, and it will be conducive to clearness to abandon altogether this term—rotation round an axis—and speak of the mirror being turned in the direction of a certain meridian of the patient's cornea, this meridian being the one perpendicular to the axis round which the mirror is rotated. Thus, when we speak of the mirror being turned in the horizontal direction, we mean that it is being rotated round its vertical axis; when we speak of its being turned in a direction up and *in* at an angle of 30° with the vertical, we mean that it is being rotated round an axis inclined up and *out* at an angle of 30° with the vertical. Adopting, then, this phraseology now, we say that in cases of M. or H. the shadow moves in the same direction ('with' or 'against') in which the mirror is turned. Further, the edge of the shadow is perpen-

dicular to the direction in which the mirror is turned. It must also be stated here that the above phenomena as regards 'with' and 'against' apply to a *concave* mirror only; with a plane or convex mirror, the directions in which the shadow moves are reversed. We can then by this method at a glance diagnose the *quality* of the refraction; but, further, we can estimate its *quantity*. To do this it is only necessary to fit the patient with a trial-frame, and put in it lenses to correct the refraction—i.e. concave or negative lenses in the case of M., convex or positive in the case of H.; in either case we find what lens causes the shadow-movement to disappear.

We know that now the eye *plus* the lens forms an emmetropic (nearly) combination, and the strength of the lens gives the amount of M. or H. The correct lens is in many cases found only after several trials, but a little practice will often enable the observer to make an approximation to it at once. With this view, he should note especially the *intensity* of the fundus reflex; if this be bright, the case is one of low ametropia (whether M. or H.); if it be dull, it is a case of high ametropia. To take an example:—

The patient's eye shows a dull fundus-reflex, and the shadow moves 'with.' The case then is one of high M. We put up a lens of, say, -7 D in the trial frame. The reflex is now much brighter, and the shadow still moves 'with.' 7 D is then not strong enough to connect the M.; we put up -9 D, and now we get no shadow at all; the amount of M. is then 9 D (nearly). On trial with test-types at twenty feet, we find the M. is actually 10 D, rather more than we found by retinoscopy; this results from the fact mentioned above, that the condition in which no shadow at all is seen is not one of exact E. but of M. of about 1 D. In all cases, it will be found that the actual M. is about 1 D *greater* than that indicated by retinoscopy, and (for the same reason) the actual H. about 1 D *less*.

To proceed now to the phenomena of retinoscopy in *Astigmatism*. In M. and H. we have seen that the direction in which the mirror is turned is immaterial, a shadow-movement being procurable in any meridian by turning the mirror in the direction of that meridian. In astigmatism, however, we get a shadow-movement in the direction of the two principal meridians *only*, and this no matter in what direction the mirror is turned. It follows that if the mirror be not turned parallel to one of the principal meridians, the consequent shadow-

movement is not parallel to the direction of turning of the mirror. This fact at once indicates that astigmatism is present, and reveals the directions of the principal meridians. These being ascertained, we proceed to examine their refraction, turning the mirror for that purpose in the direction of each of them successively. With a little practice this can be done pretty accurately, the direction in which the mirror is being turned being shown by the direction in which the circular patch of light (reflected from the mirror) travels across the patient's face. Take one of these chief meridians: Turning the mirror in its direction, we have, as a criterion of its refraction, a shadow moving parallel to it, and with edge perpendicular to it. All that has been proved of the shadow in any meridian in the non-astigmatic eye is true of this one meridian in the astigmatic: the movement of the shadow shows whether the meridian is M. or H., and the strength of glass necessary to cause the shadow to disappear gives the amount (nearly) of the M. or H. We note the lens required, and then proceed to examine in the same way the other chief meridian. Having thus determined the refraction of the two chief meridians, we put in the trial-frame the indicated spherocylindrical combination, and try the patient with the test-types at twenty feet. To get the best vision, we expect to have to slightly strengthen the spherical lens in M., and weaken it in H., and other slight changes in the strength of the cylinder and the direction of its axis may be necessary before the most satisfactory result is obtained. But, as a rule, the lens indicated by retinoscopy comes very near to the one finally chosen.

Take a case. Right eye. Dull fundus-reflex. Shadow moves 'against.' With + 8 D a well-defined shadow moving 'with' the mirror in meridian 45° up and out; no shadow seen in meridian perpendicular to this; that is, + 8 D corrects this latter meridian, + 6 D gives no shadow in meridian 45° up and out, and a faint shadow moving 'against' in meridian perpendicular to this—that is, + 6 D corrects the former meridian, $\frac{+6\text{ D}}{+1.50\text{ D cyl.}}$, axis 45° up and out gives no shadow in any meridian. The lens that gives the best vision is $\frac{+5.50\text{ D}}{+1.50\text{ D cyl.}}$, axis 50° up and out, and with this $\frac{6}{9}$ is read, v without the cylinder being only $\frac{6}{36}$.

Very often in cases of compound astigmatism the As. is not evident at first, and only appears when, in the course of correcting the apparently simple spherical anomaly, we put up a lens that nearly corrects one meridian; the shadow in the other meridian then stands out clearly. Mixed astigmatism is diagnosed at a glance, the shadows in the two chief meridians moving one 'with,' the other 'against.'

In conclusion, a few practical hints may be given. A mydriatic is often necessary, especially in cases of astigmatism. Where a mydriatic is not used, the patient should be directed to turn his eye so that the light from the mirror falls on the optic disc; in this way the greatest dilatation of the pupil is obtained. The surgeon should get into the habit of sitting always at about the same distance from the patient, and using the same intensity of light.

A dull fundus-reflex, suggesting high ametropia, may be caused by pathological changes in the media of the eye.

Irregular, broken shadows generally mean opacities of the cornea.

The retinoscopic examination must, generally, be considered only preliminary to the usual test with lenses and types at twenty feet.

A much fuller account of the method, especially in its theoretical aspect, is to be found in the *Royal London Ophthalmic Hospital Reports*, vol. x. part iii.

W. CHARNLEY.

RETRO-NASAL CATARRH is a chronic inflammatory condition of the mucous membrane lining the naso-pharynx and the posterior part of the nasal cavities. It is frequently associated with chronic nasal catarrh and granular pharyngitis. Several varieties have been described, such as the follicular, the hypertrophic, and the dry catarrhal, but they would appear to be merely stages of the same disease, and are here treated as such.

The cause of the catarrh is not altogether understood. The extension of chronic catarrh from the nose or pharynx, frequent exposure to alternating draughts of hot and cold air, the irritation of particles of dust, which are particularly apt to become lodged in this portion of the respiratory tract, and direct contagion have been regarded as exciting causes; whilst struma, syphilis, and residence in hot and damp climates are thought to predispose to it. It is much more common in America than in this country, and is there thought by Dr. Robinson to depend upon a 'catarrhal diathesis.'

Pathology.—In the earlier stages of the disease, there is simply a catarrhal inflammation of the mucous membrane; later, the mucous membrane and submucous tissue become infiltrated with inflammatory products, and the glands enlarged and stimulated to over-production, when the hypertrophic stage, or the follicular variety, of the disease is reached. Still later—it may be after a few months or many years—the mucous membrane, in consequence of the contraction of the inflammatory exudation, shrinks and atrophies, whilst its glands are destroyed to a greater or less extent. The parts now appear glazed and dry from deficiency of secretion; and in this atrophic stage the disease is spoken of as dry catarrh.

The *symptoms* vary according to the stage of the disease, but space does not permit of their being given in detail. In a well-marked case, say in the hypertrophic stage, the period at which the surgeon is perhaps most frequently first consulted, the chief complaints are of a feeling of stuffiness and obstruction at the back of the nose, a constant hawking up of a viscid, mucopurulent secretion, sometimes streaked with blood, and a peculiar alteration in the voice. At first there may be no fetor, but later the breath, in consequence of the decomposition of the secretion, becomes peculiarly foul, and is then one of the patient's chief annoyances. Headaches, especially in the occipital region, deafness, and dyspepsia where the mucus is allowed to pass into the stomach, may also be present; and epistaxis may from time to time occur. Should chronic nasal catarrh co-exist, there will likewise be a discharge, and often an offensive one, from the nose.

On looking into the throat, the mucopurulent secretion will often be seen trickling down the posterior wall of the pharynx, which may present the characteristic appearances of granular pharyngitis. In the rhinoscope, the mucous membrane of the naso-pharynx, and especially that about the vault, appears thickened and often paler than natural, while the hypertrophied glands give it a peculiar mammillary and granular appearance, similar to that of granular pharyngitis. The mucous membrane lining the posterior pillars of the fauces, the back of the palate, and the orifice of the Eustachian tubes, usually presents similar changes, whilst that covering the sides of the septum is frequently cedematous, and that over the posterior ends of the inferior spongy bones greatly hypertrophied. The hypertrophied ends of these bones appear in some instances

as distinct tumours, having a globular shape and a purplish-red colour, and, together with the cedematous septum, may completely occlude the choanæ. The above condition of the mucous membrane is often obscured by the presence of the viscid mucus, and it may not be until this has been removed with the spray or syringe that the actual state of the parts can be made out. In the atrophic stages of the disease, the naso-pharynx appears more roomy than natural, and glazed and dry; whilst the mucopurulent secretion, in consequence of the atrophy of the glands, is not cast off, but becomes inspissated, forming greenish and adherent crusts, beneath which the retained secretion undergoes decomposition and gives rise to the horrible smell. The nasal chambers, if involved in the disease, present similar appearances when viewed from the front. Ulceration does not usually occur in the course of chronic retro-nasal catarrh. Should such be observed in the rhinoscopic mirror, the case will probably be one of a syphilitic nature, and dead bone will, in the majority of instances, be discovered if further search be made for it.

Treatment.—This should be both constitutional and local. When convenient, the patient should reside in a dry and equable climate, and all sources of irritation, —as dust or noxious vapours, alternations of heat and cold, and tobacco and spirits—should be avoided. Internally, cubebs, which appears to have a marked influence on the secretions of the pharynx, should be given in large doses, and chloride of ammonium, ammoniacum, arsenic, salicylic acid, and sulphur may be tried. Where there is evidence of syphilis or struma, appropriate remedies should of course be given. Locally, the parts should be frequently cleansed by weak carbolic or alkaline sprays, and subsequently astringed by sprays of sulphate or chloride of zinc, or tannin; or by the insufflation of powders of eucalyptus (1 part to starch 2 parts), iodoform, catechu, and the like. These remedies should be applied by the brush, the insufflator, or the post-nasal spray apparatus, the nozzle of which must be passed well behind the palate. Syringing, except when the crusts are very adherent, is to be deprecated, and the nasal douche should on no account be employed, as its use is not only attended by the risk of setting up disease in the middle ear, but it also induces a soddening of the mucous membrane, and does not reach the whole of the affected parts.

Where there is much hypertrophy of the posterior ends of the inferior spongy bones,

these should be scored with the post-nasal galvano-cautery, directed by the mirror, and the scoring repeated at intervals of a week to a fortnight, till the parts have been reduced to their normal size. Or, if preferred, the hypertrophied tissue may be removed at one sitting by Jarvis's snare, the wire of which is passed through the nostril, and guided over the end of the spongy bone by the finger behind the palate. Local anæsthesia should be induced by painting a 20 per cent. solution of cocaine over the mucous membrane before using the galvano-cautery; but chloroform had better be given if the snare is used. Should a hypertrophic condition of the mucous membrane of the anterior portions of the nasal cavities also exist, the galvano-cautery should be applied to the inferior spongy bones, the septum being protected by Shurley's ivory speculum; or the hypertrophic mucous membrane may be removed from over the inferior spongy bone by Robinson's forceps; or the whole bone cut away by the nasal pliers. The author can speak from personal experience of the value of the galvano-cautery in these cases, and much prefers it to the rougher treatment with the forceps or pliers. At the same time, he is bound to say that he has never seen any harm follow the evulsion of the inferior spongy bone, and this treatment is certainly more rapid than that with the galvano-cautery.

When the disease has reached the atrophic stage, a complete cure must hardly be expected; the distressing symptom of fetor can, however, be relieved by the use of deodorising and disinfecting sprays, and the sense of dryness by the internal administration of salicylic acid and cubebs. The insufflation of a powder of salicylic acid 1 part, gum acacia 2 parts, will often take away the fetor in a few hours. Should the anterior part of the nasal cavities be also affected by the atrophic form of catarrh, the like remedies should be applied by the anterior nasal spray-producer; whilst, at night, Gottstein's nasal tampons should be inserted, or an iodoform and eucalyptus bougie be allowed to dissolve in each nasal chamber.

W. J. WALSHAM.

RETRO-PHARYNGEAL ABSCESS.

An abscess in the connective tissue between the pharynx and the spine.

Cause.—It may be seen at all ages, but is most frequent in children, occurring even in infants; in them it is often idiopathic. It is said to be more frequent in boys than in girls (Cohen). When idiopathic, a history

of tubercle or syphilis is generally obtainable. Most commonly it is due to spinal caries, and is then chronic (*see* CARIES OF THE SPINE); but may complicate quinsy, and follow acute pharyngitis, especially after the exanthems, acute phlegmonous sore-throat, erysipelas, and syphilis; this last even occasioning caries at the same time. Injury to the pharynx from food, hot liquids, irritants, foreign bodies—e.g. impacted false teeth—may cause abscess.

Pathology.—Predisposition to inflammation of this part exists in its lymphatic structure, its constant mobility, and its liability to injury and variations in temperature. When idiopathic, suppuration begins in the submucous adenoid tissue (Bókai); when it begins in the deeper connective tissue, it is likely to be tubercular (Cohen). Caries of the front part of any of the cervical vertebræ determines the presence of pus behind the pharynx, though it often burrows down and becomes post-mediastinal. Retro-pharyngeal abscess is usually on one side of the middle line, and is accompanied by induration that can be felt below the angle of the jaw on the same side. It may point in the mouth, or on the side of the neck, and has been known to follow the brachial nerves to the axilla. The presence of the abscess causes mechanical dyspnoea and dysphagia, and by bursting may flood the larynx and suffocate. When post-oesophageal, it may open into the lung or oesophagus. Other complications are oedema of the glottis, and opening into the internal carotid artery. Sequestra are often discharged by the mouth, when caries is the cause of the abscess.

Symptoms and Diagnosis.—When acute, there is general pyrexia, with local heat and tenderness, dysphagia, huskiness, stiffness in the neck, and dyspnoea which is relieved by the erect posture. When sleeping, the patient snores as in tonsillitis. As the abscess enlarges, the head is thrown more backwards, and a tender swelling appears at the angle of the jaw. The mouth is opened with difficulty, and there may be profuse secretion of mucus (as in oesophagitis), which must not be mistaken for salivation. A fluctuating and very tender and unilateral swelling will be seen or felt in the pharynx, and when in the nasopharynx it pushes down the soft palate. The more laterally placed, the less the dyspnoea and the greater the resemblance to quinsy.

The chronic form, due to caries, often gives rise to no symptoms until there is dysphagia or dyspnoea; possibly the swell-

ing at the angle of the jaw may first attract attention; or the abscess may have become post-mediastinal, and even have opened into a bronchus or the pleura before it is discovered. Excepting the accompaniments of acute inflammation, the condition is as detailed above; and, as manipulation is less painful, fluctuation between the external swelling and that in the pharynx may at times be made out. Left to Nature, the abscess may increase so as to necessitate interference, or it may burst in the mouth, in the chest, or externally; or it may sometimes resolve. Parts of the cervical vertebrae may come away through it. When symptoms of cervical caries are obscure and unnoticed, the abscess may never be recognised; sudden death has been known to occur from atlanto-axoid disease where it was unsuspected, and the autopsy alone revealed a post-pharyngeal abscess.

Diagnosis.—The acute form of abscess in children may be mistaken for croup; but the dyspnoea is relieved by sitting up, is very intermittent, and unaccompanied by the crowing noise of croup. Dysphagia is a prominent symptom, the child even declining to try to swallow. Inspection of the throat reveals the condition at once. The chronic form has to be distinguished also in children from sarcoma; this last grows rapidly, does not fluctuate, though it is soft, and its surface is nodular or irregular. See PHARYNX, Tumours of the.

Treatment.—Retro-pharyngeal abscess should be evacuated as soon as possible. The old method with trocar and canula through the mouth is for many reasons unsatisfactory. A vertical incision into the tumour, with a bistoury guarded up to its point with sticking-plaster, is easily made, but the left forefinger must hold down and push back the tongue at the same instant, so as to force the epiglottis over the laryngeal aperture, or the first gush of matter may enter the windpipe. When pointing, the finger-nail has been employed to open the abscess. As in other wounds made in the oral cavity, there is but little risk of septicæmia; yet, if desired, the abscess can be opened aseptically by dissecting down upon it behind the sterno-mastoid, and thrusting dressing-forceps into it. See ANTISEPTIC SURGERY. The simpler plan of opening it in the mouth has the advantage of easily allowing a sequestrum to be removed. The writer does not think the advantages of the external method commensurate with its difficulty of performance and more serious character.

C. HILTON GOLDING-BIRD.

RHEUMATOID ARTHRITIS. See CHRONIC RHEUMATIC ARTHRITIS; OSTEO-ARTHRITIS.

RHINOPLASTY.—Under this heading is included a number of plastic operations performed for repair of the nose, in cases of deformity and partial or total loss of that organ. The disfigurement requiring an operation of this kind may be the result of congenital malformation, of injury, or of surgical operation, but in most instances is due to syphilitic, tubercular (lupoid), or cancerous ulceration. The disfigurement, in severe cases of the latter class, is caused partly by destruction of more or less of the nose, and partly by contraction of cicatricial tissue. Although the most favourable conditions for the success of a plastic operation are presented by this region, still the results of rhinoplasty are not usually very satisfactory. The soft parts around the nose are very vascular and well-organised, and thick flaps composed of several layers of varied tissue may be brought over the defect from almost every quarter; but notwithstanding this, it too often happens that, as was pointed out by Denonvilliers, a repulsive deformity has been converted into one that is ridiculous. It has been asserted, however, that the loss of smell and taste, caused by complete destruction of the nose, may be overcome to some extent by supplying a new nose, and there can be no doubt that the patient is thus rendered less liable to attacks of laryngeal and bronchial catarrh. The appearance of a prothetic apparatus of some foreign material is no less unpleasant, especially during transient changes in the vascularity of the adjacent sound parts.

The results of a rhinoplastic operation, with regard to the relief of deformity, will depend much more on the extent of osseous than that of cutaneous loss. If the bones of the nose be preserved, there is always a good chance of restoring a prominent and sightly organ, though most of the skin may have been destroyed. In cases of destruction of the osseous framework of the nose, on the other hand, the surgeon cannot expect to do more than cover the open chasm by a flap, which will remain almost on a level with the cheeks. With regard to the condition of the soft parts, from which it is intended to take one or more flaps, mere superficial cicatrization would not interfere with the success of the operation. Indeed, scarred skin under certain circumstances, as in the restoration of an ala, would be more suitable material for a flap than skin that is quite sound. When, however, the skin around

the nose has been almost completely destroyed and converted into dense cicatricial tissue, as after a deep burn, the flap would shrink to a considerable extent, and very probably slough. The most unfavourable conditions for rhinoplasty are those in which the nose has been destroyed by syphilitic ulceration or a burn. In cases of destruction by lupoid or cancerous ulceration, by which usually only the soft parts of the organ are destroyed, the prospects of success are more promising.

It has been laid down as a strict rule that, before rhinoplasty be practised for deformity from specific ulceration, an interval of at least six months should follow the disappearance of all signs of active disease. The patient at the time of the operation should be quite healthy, and placed in the best possible hygienic conditions. The complications to be feared during the after-treatment are sloughing of the flap, renewal of the specific ulceration, secondary hæmorrhage, and erysipelas.

For restoration of a completely destroyed nose, the surgeon may transplant a flap from some distant part of the body, as in the old Tagliacotian or Italian operation, or transpose one from the forehead. The former procedure, which, as is well known, consisted in taking a flap of skin from the inner surface of the arm, had from the time of Dieffenbach remained obsolete and of simply historical interest until recently, when it was again performed with much success by Sir William MacCormac in a case of partial loss of the nose with cicatricial deformity of the face, and also by Mr. Hardie of Manchester, who took the flap from the flexor surface of the thumb. The flap has been taken also from the forearm. Though disfigurement of the forehead or cheeks will be thus prevented, the after-treatment in the Italian operation must always be attended with much difficulty, and be found extremely irksome and disagreeable by the patient. The skin of the arm is not so suitable for rhinoplasty as that of the forehead. The primary retraction is certainly very considerable, and, according to Dieffenbach, the subsequent atrophy also was greater in flaps derived from the former source.

In the Indian or frontal operation, performed most frequently by German and English surgeons, a large flap is taken from the forehead and twisted downwards on an inferior attached pedicle, so as to cover the defect. In the first stage of this operation, a commensurate model of the new nose is formed of stiff paper or cardboard, which is

then flattened out on the middle of the forehead. A flap of the same shape as the flattened model, but larger to the extent of a quarter of an inch in every direction, is next mapped out by a deep incision down to the pericranium, and dissected away until it is attached merely by a narrowed root near the internal canthus, on one or the other side. The broad base of this flap usually falls just within the region of the hairy scalp. The hæmorrhage from the large wound thus formed having been arrested, the edges of the defect are pared, except below near the lip, the whole thickness of the soft parts being divided. In this dissection the knife should be carried obliquely from without inwards, so as to cut away more of the deeper portion of the skin than of the surface, and to form a shelving wound around the nasal orifice. This is usually the second stage in the operation, but some surgeons commence by refreshing the edges of the defect, and afterwards take up the frontal flap.

In the third stage, the triangular flap, still attached by its pedicle, is twisted outwards, and then brought downwards, over the defect, to the pared margins, to which its edges are fixed by sutures. The edges of the large wound in the forehead are next approximated by needles and twisted sutures. The columna of the new nose may be formed, either by a narrow process of skin extending from the broad base of the frontal flap, or by a separate tongue-like process cut from the middle of the upper lip, and turned upwards to be fixed by its free end to the tip of the new nose, whilst the other extremity remains attached near the lower margin of the nasal orifice. The lower edge and the alæ of the new nose are elevated at first by pieces of lint, and afterwards, during the healing process, by metal or 'gum-elastic' tubes. The seat of operation should be covered by some simple dressing, and over this a thick layer of cotton-wool. After an interval of six weeks, when the circulation in the new nose has been established, and œdema and signs of congestion have disappeared, the pedicle may be divided, and some small plastic operation be performed for relieving the deformity caused by its prominence.

The best material for the sutures used in this operation for fixing the flap is fine silver wire. Silk often causes some slight sloughing around the punctures, and catgut soon becomes soft, and either melts or gives way. The use of stout needles, with the object of elevating the flap, is liable to

cause too much traction on the tissues around the defect, and also to interfere with the circulation in the new nose.

The chief source of failure in this operation is obstruction to the blood-supply of the transposed frontal flap, through torsion of the pedicle. With the view of reducing this torsion as far as possible, many modifications have been proposed in the position of the pedicle and also of the flap. Lisfranc held that one of the incisions limiting the pedicle should be carried half an inch lower than the other, so as to reach almost to the upper margin of the defect; whilst Langenbeck forms the pedicle to one side of the median line, and commences the two incisions just above the internal canthus. Other German surgeons carry the outline of the whole flap more or less obliquely across one side of the forehead, and, in extreme forms of this modification, the long axis of the flap is almost parallel to the line of the eyebrow.

The inclusion of periosteum in the frontal flap, as practised by Langenbeck and Ollier, with the object of rendering the new nose more prominent, does not seem to have been followed by very good results; and, as was pointed out by Serre of Montpellier, might excite inflammatory mischief in the frontal bone, and even give rise to some encephalic complication.

Ollier has endeavoured to impart a good shape to the new nose formed by a frontal flap, by transplanting, in connection with this flap, one of the nasal bones; and instances have been recorded in which Hardie of Manchester, and Sabine, an American surgeon, practised the Italian method, and transplanted the last phalanx of the forefinger.

Rhinoplasty by transposition of lateral or facial flaps—a method to which much attention has been paid by French surgeons—will be found suitable in cases in which the upper part of the nose remains intact. This plan of operation, which is a very old one, and was described by Celsus, has of late years undergone a great variety of modifications. Its simplest form is presented by the operation practised by Syme, which consists in taking two flaps of skin from the cheeks, uniting these in the middle of the face by three or four sutures, and then fixing the outer edges on each side to the raw surface, at a proper distance from the nasal orifice. The wounds of the cheek admit of being nearly closed by a stitch through the edges of each, and what remains of them is of use by the contraction of the granulating process depressing

the hollow at the side of the nose, and thus increasing its apparent elevation.

In Nélaton's operation, two thick flaps, each with a pedicle attached near the lacrymal sac, are brought downwards and inwards over the defect, and stitched together in the median line. In making these flaps, the periosteum is removed from the nasal process of the maxillary bone, so that the resulting scar may be dense and closely attached to the bone, and so rendered incapable of dragging on the new nose. A further attempt to prevent flattening of the organ is made by passing a stout needle through both alæ, and compressing these by the action of a weak metallic spring. In the many modifications of this method, the shape and direction of the flaps are much varied. In some cases, the soft parts of the face have been simply glided over the defect after free separation from the subjacent bone. The chief objections to the so-called French method of lateral flaps are the severe primary hæmorrhage, the risk of secondary hæmorrhage, the disfigurement caused by a linear cicatrix in the middle line of the new nose, and the tendency in the organ to become flattened through tension of the soft parts of the cheek.

A combined frontal and facial rhinoplastic operation, first proposed by Verneuil and practised in this country by Mr. F. Mason, consists in turning down over the defect a frontal flap with its raw surface outwards, and covering this by two flaps taken from the cheeks.

In 1867 Mr. John Wood reported a case, in which he had formed a new nose by taking a broad flap from the upper lip. This, after it had been elongated by separation of the cutaneous and mucous layers extending as far as, but not through, the border of the lip, was turned upwards and fixed by sutures to the upper margin of the nasal defect, and, finally, its anterior raw surface was covered by lateral flaps taken from the cheeks.

In cases where but one or both alæ have been removed by injury or ulceration, a flap may be taken from the sound portion of the nose. Where one ala has been removed, the flap is usually taken from the opposite side, and where the end of the nose has been destroyed on both sides, a square flap has been taken from the bridge and turned downwards, with the epidermic surface directed towards the nasal cavity. In cases of this kind, a flap may be taken from the upper lip or even, as proposed by Michon, from the mucous membrane of the nasal septum. Almost innumerable modi-

fications of the rhinoplastic operation by nasal flaps have been devised by Dieffenbach, Langenbeck, Denonvilliers, Busch, and others.

When the nose has been partially removed by injury or surgical operation, immediate rhinoplasty is not, as a rule, indicated. According to Verneuil, in cases of removal of a portion of the skin without perforation of the cartilage, in which the loss is not excessive, the surgeon should leave the wound to heal by granulation, and not attempt immediate union or cover it by a cutaneous flap.

Several operations have been devised for the relief of the disfigurement caused, in cases of destruction of the bony framework only, by depression and flattening of the soft parts of the nose. The aim, in most of these procedures, is to raise and approximate the two wings of the nose after vertical incision of the organ itself, as in Dieffenbach's method, or after extensive separation of the attached margins of the organ and of the soft parts of the cheeks from the subjacent bone, as in the modification devised by Sir William Fergusson. In the latter operation, the alæ having been separated from the parts beneath, and the knife carried on each side between the skin and the bone as far as the infra-orbital foramen, two long needles were passed through the nose from one cheek to the other, and their ends twisted over a small piece of leather applied on each side, so as to cause the cheeks to come closer to each other, and thus render the nose prominent.

In cases of abnormal shortening of the nose from imperfect development, Weir of New York proposes to make a free incision in the soft parts across the middle of the organ, and then, after drawing down the lower part, to fill up the large gap thus formed by flaps taken from the cheeks.

W. JOHNSON SMITH.

RHINOSCOPY.—Inspection of the nose—rhinoscopy—may be practised from the front (anterior rhinoscopy), or from behind (posterior rhinoscopy). For both methods of examination, to make them successful and complete, good illumination and gentle handling of the instruments are essential, even more so than in laryngoscopy.

ANTERIOR RHINOSCOPY.—To obtain a good view of the anterior parts of the nose, direct or reflected rays of light must be thrown into the patient's nose in the manner described in the article on **LARYNGOSCOPY**. The relative positions of the surgeon, the patient, and the source of light,

and the methods for illuminating the parts, are identical with those described in that article. Dilatation of the nostrils is necessary for complete examination of all the parts accessible to inspection, and to effect this, innumerable nasal specula have been invented. The writer has found B. Fränkel's fenestrated instrument, and the longer variety of Duplay's cone-shaped bivalve speculum, both of which are provided with a screw arrangement to open the blades, most serviceable, and, indeed, sufficient for all ordinary purposes. The former is especially useful for examination of the anterior and lower, the latter for inspection of the upper and posterior parts of the nose. The patient's head being slightly inclined backwards, the speculum is to be gently introduced into one of the nostrils (which must have been well cleaned previously); its blades are to be opened, by turning the screw to as full an extent as possible without hurting the patient, and light is then thrown into the cavity, either directly, or from the frontal mirror attached to the surgeon's forehead. When a sufficient view has been obtained of the parts which are immediately in sight, the operator, whilst retaining the speculum with one hand in the nostril, places his free hand on the patient's vertex, and by gentle pressure causes him to bend his head in any desired direction, slightly downwards, upwards, to the right and to the left, the inspection being continued meanwhile. This is necessary in order to obtain a view of all that is really visible, and it is more advisable to direct the movements of the patient's head by touch than by words, in order that the movements may not be too sudden or too violent. After completing the inspection of one nostril, the other is examined in the same manner.

The appearances vary very considerably in different cases. The larger part of the septum, which but rarely appears as a thoroughly straight vertical plate and is more frequently deflected into one or even both nostrils, can be satisfactorily brought into view. The colour of its mucous membrane is, usually, yellowish-red. The lower turbinate bone, which is the most conspicuous object after introduction of the speculum, appears as a bright red, oval or nearly semi-globular bulging, the floor of the nose as a rather flat or slightly excavated groove. The anterior part of the middle turbinate bone can mostly, but not always, be brought into view by the patient bending his head slightly backwards, and in exceptional cases a small part of the

upper turbinate bone may be seen. In cases of *ozæna*, when considerable atrophy of the lower turbinate bones has taken place, it is often possible to look through the nose into the naso-pharyngeal cavity, and to observe the play of the tubal muscles. Professor Zaufal has lately devised long funnel-shaped nasal specula, which are intended to render such inspection, as well as examination of the posterior parts of the nose and certain operations, possible in all cases.

The frequent irregularities of the configuration of the interior of the nose, the physiological deviation of the septum, the common occurrence of exostoses, &c., often make it rather difficult for the beginner to correctly interpret what he sees. Practice alone can lead to more precise information. Examination by means of the blunt nasal probe, under the guidance of the eye, ought under all circumstances to complete the results of mere inspection.

POSTERIOR RHINOSCOPY is an excellent, though not always applicable, adjunct to digital exploration of the naso-pharyngeal cavity. Its method consists in the introduction into the patient's mouth and behind the soft palate of a small laryngeal, or, as it is called here, rhinoscopic mirror, with the reflecting surface upwards, when, after proper illumination of the mirror, a reflected image of the parts above will appear on its surface. Simple as this proceeding appears to be, it is in reality sometimes very difficult. Much depends upon the co-operation of the patient, and this is not always easy to obtain. The better educated and less nervous the patient, and the larger his pharynx in its antero-posterior diameter, the more easy will be the examination. The main difficulties dependent upon the patient are threefold—(a) involuntary retraction of the velum towards the posterior wall of the pharynx (usually associated with too forcible an opening of the mouth and faulty breathing, or involuntary arrest of respiration); (b) refractoriness of the tongue, the middle and posterior parts of which constantly arch upwards; (c) excessive irritability of the palate, uvula, and posterior wall of the pharynx, causing spasmodic contraction and retching, so soon as these parts are, however lightly, touched. Previous local application of a strong cocaine solution—the writer uses by preference a 20 per cent. solution—will entirely overcome the last-named difficulty. With some practice and patience, however, such application will generally be superfluous. It is essential to teach the

patient to breathe as quietly and naturally as possible *through the nose*, the object of this being that the soft palate should be entirely relaxed. This is indispensable for the success of the examination. A great many palate-hooks, uvula-nooses, and elastic tractors have been invented, with the object of forcibly drawing the soft palate forward, and thus laying the naso-pharyngeal cavity open to inspection. In some very tolerant individuals they may be useful; in almost every case, however, in which posterior rhinoscopy is at all possible, more will be obtained by patience, gentleness, and repetition of the examination, than by artificial means.

The relative positions of the patient, the surgeon, and the source of light are the same as in laryngoscopy. The patient is told to open his mouth, to keep his tongue in, and to breathe quietly through his nose; forcible respiration is as much to be deprecated as holding of the breath. The surgeon now introduces the warmed rhinoscopic mirror, the reflecting surface of which (not more than about five-eighths of an inch in diameter), is directed upwards to the right or left side of the uvula, into the pharyngeal cavity proper. He must guard carefully against touching the posterior part of the tongue, the velum palati, the palatine arches, and the posterior wall of the pharynx. Instead of a small laryngeal mirror, Michel's rhinoscope may be used. In this instrument, the angle of the mirror to the shank can be changed to any desired extent by a spring in the handle, while the shank remains perfectly immobile. The light is thrown on the rhinoscope from the frontal mirror or other source of illumination. The writer's electric rhinoscope (see *Lancet*, March, 1885) dispenses with the difficulty of the last-named proceeding. If a laryngeal mirror be used, its shank will usually answer as a tongue-depressor, but, in some cases, it will be better to gently but firmly depress the tongue with a spatula held in the operator's left hand, whilst his right hand directs the rhinoscope.

A complete inspection of the naso-pharyngeal cavity can only be made by altering the position and slanting the mirror, the rhinoscopic image being a compound picture. It will often be necessary to introduce the mirror several times, before this purpose is achieved.

When the mirror is held more in the vertical position, the choanæ, or posterior nares, come into view. The posterior aspect of the nose shows in its middle the septum, forming a thin, straight, almost white pro-

jection, which above passes over, in the form of two symmetrical Roman arches, into the vault of the pharynx. It is of practical importance to know that these arches are visible in every normal rhinoscopic image; should they not be seen, this proves that they must be obscured by some abnormally developed tissue. On both sides of the septum the posterior ends of the three turbinate bones appear, the middle bone being the most conspicuous. Their configuration is somewhat variable; the superior turbinate bones are rather horn-shaped, the middle oblong, the lower rounded. Their colour, on the whole, is pale, especially that of the middle turbinate bones. Between them are visible, more or less distinctly, the three nasal meatuses. When the mirror is held in a more horizontal position, the vault of the pharynx comes into view. Its appearance is often rather irregular and rough, owing to the adenoid tissue by which it is covered. On slanting the mirror, held at an angle of about 130° to the horizon, and inclined towards one side, the internal opening of the Eustachian tube, with its folds of mucous membrane, and Rosenmüller's fossa come into view. Below and in front, the upper surface of the velum, in the middle of which the so-called 'uvula cushion' is visible, forms the lower border of the rhinoscopic image. FELIX SEMON.

RIBS, Fractures of the.—These are among the most frequent of all bone-injuries, forming about a tenth of all the fractures we are called on to treat. They are more common in the male than in the female, on account of the greater exposure of the male sex to violence; more frequent in the middle-aged and old than in young people, on account of the greater elasticity and softness of the bones in the young; and they occur more often about the seven upper ribs than in the five lower, on account of the more rigid way in which these ribs are connected to the sternum. In children, the fracture is very often incomplete from the way in which the rib is driven inwards; in such cases, the part of the rib towards the pleura may be fractured, while the outer part remains intact. In this way, damage to the pleura may sometimes arise, while the rib remains apparently intact.

The ribs are most commonly fractured by the application of some strongly compressing force. When the force is applied over a small surface, the fracture is said to be by direct violence, as takes place when a rib is fractured by the blow of a rope's end, or

of a fist, or when the body falls upon some projecting point. When the force is applied over an extensive surface, as when the ribs are fractured by a wheel passing over the chest, which thus caves in, the fracture is said to be by indirect violence, the rib in this case fracturing at a distance from the point where the violence is actually applied. The distinction is only of importance in relation to the number of ribs fractured. In fractures produced by indirect violence, the number is likely to be much greater than when produced by direct violence. On the other hand, direct violence is apt to drive the end of a single rib further into the cavity of the thorax, and thus is more likely to damage the thoracic viscera. Fractures of the ribs are also produced by muscular action, as in the act of coughing or sneezing. It is possible that some of the apparently spontaneous rib-fractures of old people are produced in this way.

The number of ribs fractured depends very much upon the nature of the injury. In fracture produced by direct violence, only one side of the body is generally affected; in those produced by indirect violence, one or both sides may be affected, and a rib may even be broken in two places. Fractures of the ribs are scarcely ever compound, except from gun-shot injury.

The *symptoms* of a fractured rib are often rather indefinite. There is pain at the seat of fracture, undue mobility, detected principally by pressure upon the end of the rib, and crepitus, which is often difficult to detect, but which is best done by placing the hand over the chest and making the patient breathe. In this act, a little alternate pressure and relaxation of the hand will often make the crepitus apparent, when it is otherwise difficult to make out; or it may be detected by placing the ear or stethoscope to the chest, and causing the patient to take a full inspiration. Difficulty in breathing and coughing, and more or less 'stitch in the side,' are also commonly present. The respiration is mostly diaphragmatic. The cough is very peculiar; it is slight and suppressed but frequent, and troublesome from the pain caused by it. This pain is probably due to some irritation of the intercostal nerve at the seat of fracture.

Fracture of the ribs is often complicated by damage to the internal viscera. The pleura is the part most frequently injured, and after this the lung. But many other parts are also occasionally damaged. Thus, a case is on record in which a single rib

was fractured by the end of a rope flying loose. The fractured piece was driven in through the pericardium and pierced the apex of the heart, causing almost immediate death. The diaphragm and liver are not infrequently damaged by fractures of the lower ribs, the spleen less frequently so, unless enlarged into an 'ague-cake,' while fractures of the eleventh and twelfth ribs may rupture either the ascending or descending colon. Injuries to the pleura and lung give rise to hæmothorax and emphysema, more or less general. See EMPHYSEMA; HÆMOTHORAX; LUNG, Wounds of the; PERICARDIUM, Wounds of the, &c.

Treatment.—The object of the treatment should be to immobilise the fractured ribs, so as to put them in the most favourable state for repair. This is best done by fixing broad bands of adhesive strapping (about two inches wide) from the sternum to the spine. These bands should overlap freely, so that a fair *thickness* of plaster be formed, thus acting as a kind of splint to the side of the chest, causing it all to move together in the act of respiration. If many ribs are fractured, and it is desirable to form a more solid splint or mask for the side of the chest, one or two thin pieces of light wood may be placed outside this strapping at right angles to the course of the ribs, and united to the layer of strapping beneath by other layers laid on superficially to them. This aids in making the whole side of the chest move as one piece, and is especially useful, combined with pads, where the fracture is depressed, and it is thought desirable to attempt to lift the depressed ends out of the chest. Some surgeons prefer to put a single piece of strapping over the whole of the side of the chest. This, however, never fits to the surface as well as the strips, and, if more thicknesses than one are considered desirable, it cannot be laid on so uniformly. Some surgeons, again, prefer to make the strips of plaster surround the whole chest, and some apply a bandage moderately tightly round the chest, even in cases where only one side is injured. This plan has the disadvantage of limiting the movements of both sides of the chest, whereas it is for the comfort of the patient to leave the respiratory movements of the uninjured side as free as possible.

The use of the bandage, though common, is in some cases not absolutely free from risk. Flannel is usually chosen, as being more suitable from its slightly elastic texture. But the writer has seen more than one case in which this rather elastic bandage, from being too tightly applied, has so

compressed the chest that it has caused the fractured ends of the ribs to be driven in, so that they wounded the pleura and the lung. An elastic bandage then should be applied with only very moderate pressure, and may generally be dispensed with altogether. The sensations of the patient may, however, be taken as the best test of its utility. If grateful to him, it is certain it is doing no harm, and may be continued; but if it causes oppression and pain it should at once be taken off. Indeed, some patients cannot bear anything upon the chest, and prefer simply to lie motionless in bed. Other methods of treatment have been used—as, for example, a kind of vest made to fit the body very closely, and to be suspended from the shoulder. This, however, is not so efficient as the plaster method.

Constitutional treatment will be necessary in many cases, where the patient is irritable or suffers much pain. An uncomplicated case of fracture will not generally require anything, but if it be complicated by any damage to the pleura or lung, it may be necessary to give small doses of sedatives, combined with expectorants and diaphoretics. Of these, the following is a most useful combination:—℞ Tinct. scillæ, ℥v.; Vin. ipecac., ℥v.; Tinct. camph. co., ℥xx.; Vin. antimonial., ℥x.; Liq. ammon. acet., fʒss.; Aq. chlorof. ad fʒj. M. Ft. haust. 2ndis horis sumendus.

If the fracture occur in very old people suffering from chronic bronchitic conditions, more stimulant expectorants are required, and carbonate of ammonia (gr. v. doses) with infusion of senega (fʒss. doses) may be substituted for the squill and acetate of ammonia. In such cases, putting the patient into a steam tent is often a very great relief to him. Where there is evidence of much intra-thoracic inflammation in younger persons, leeches may sometimes be advantageously applied to the chest, and even the advisability of venesection be considered. This method of treatment has almost disappeared from practice of late years, but the writer has seen some few cases in which the patient was in a state of great distress, with considerable dyspnoea, oppressed pulse, and much blueness and congestion of the face, in which a moderate venesection most markedly relieved the symptoms.

The *prognosis* in uncomplicated cases of rib-fracture is very favourable. The fracture nearly always unites by bony union, but often a considerable amount of callus is formed, from the necessary mobility due to the act of respiration. Sometimes a case

of non-union will occur, with possibly abscess and necrosis. Such cases generally indicate some predisposing constitutional condition. The prognosis is least favourable in old bronchitic persons. In these patients, a considerable secretion of mucus normally goes on from the bronchial tubes, and this is expectorated by frequent fits of coughing. After a fracture of the ribs, the pain on movement causes the cough to become suppressed, the expectoration of the mucus no longer takes place, and thus accumulation goes on to such an extent as to choke the smaller tubes and lead to death by apnoea. In fractures of the ribs, complicated by injuries to the internal organs, the prognosis depends upon the organ injured. If the diagnosis be doubtful at first, it is safer, for purposes of treatment, to assume that the major injury has occurred, and to treat the patient accordingly, until the diagnosis has become clear from the after-history of the patient. Emphysema occurring after a fracture is not generally an unfavourable sign; it quickly absorbs if left to itself. H. G. HOWSE.

RICKETS may be defined as a constitutional dyscrasia resulting from general malnutrition. It is peculiar to infancy (perhaps to the fetus) as regards its initiatory stages; and, in its later ones, chiefly characterised by changes in the texture, chemical composition, and outward form of the bony skeleton, and by altered function in other organs, transient for the most part, but occasionally permanent. Although the disease has been carefully studied in all its stages, the earliest beginnings are still quite matters of conjecture. Rickets is said to occur 'in every quarter of the globe' (Senator.) The writer has himself seen it in almost every European capital, and in the South African colonies, where the summer lasts nine months, and where overcrowding, fogs, and deficient sunlight are quite unknown. It is especially common among the manufacturing population of Yorkshire and Lancashire; it is found at places on the sea coast, as well as inland. There can, however, be no doubt that rickets is chiefly a disease of large cities, and that its development is favoured by overcrowding, neglect of sanitary and hygienic precautions, and by a cold damp atmosphere, which compels people to shut themselves up in ill-ventilated habitations.

Guérin, Storch, and especially Bednär and Ritter, admit *hereditary influences* in its production, and regard the occurrence of congenital rickets as an argument *ad hoc*.

The writer has seen many cases of direct transmission from parents to children, and at least one case of transmission from the grandparents. The disease, nevertheless, is not generally allowed by clinical teachers in this country to be hereditary. Of 1,000 children under three years of age, including babies in arms, examined in the out-patient department of the East London Children's Hospital—many of whom did not come as patients but simply accompanied their mothers—800 at least bore some traces of rickets; many of these were brought on account of pronounced rickets, but in many others the diathesis showed itself in its less generally acknowledged forms—enlargement of radial epiphyses, slight beading of ribs, late closure of fontanelles, or general backwardness. These children—boys and girls—brought up under conditions (to be presently described) which favour the development of rickets, will grow up, and in due time intermarry. Their children, bred and born under like circumstances, must surely inherit a stronger predisposition to the diathesis than the children of other persons, not so affected in their youth. The growing frequency of the milder forms, and their appearance under surroundings not usually associated with rickets, are only to be explained by this hereditary influence. Jenner 'has no facts to prove that rickets is hereditary'; but, like other authorities, admits that all those conditions which deteriorate the health of the parents, of the mother especially, render the children liable to rickets. Thus, frequent pregnancies, disparity of years in either spouse, advancing years, late marriages, irregular habits of life, acute illnesses, chronic disease (scrofulosis, tuberculosis), inherited syphilis, starvation in the parents—each and all exercise deleterious influences on development of the offspring, which predispose them to rickets. Thus, it is obvious why the poor should not alone suffer from this diathesis; on the contrary, rickets is found among all classes of society, although the advanced and fatal forms are most common among the poor.

The influence of heredity, however, is further proved by the frequency with which many members of the same family suffer, even without the immediate influence of that environment which is known to develop rickets. The absence of any persistent symptoms in the parents is no argument against this view, any more than it would be in the case of gout, or rheumatism, or other disease, the manifestations of which are temporary and generally fleeting.

Period of Onset.—Some of the signs of rickets are not infrequently found in foetuses (a condition, however, not to be confounded with *foetal rickets*, which will be briefly considered further on), and still more frequently in children at birth. These signs consist in curvatures of the long bones, with enlargement of their epiphyses; beading of the sternal ends of the ribs, with a tendency to pigeon-breast; an unduly open condition of the fontanelles and sutures, with enlargement of the head. More marked and more generally acknowledged signs have been observed a few weeks later; thus, Gee says: 'Unquestionably beading of the ribs may occasionally be found in infants of only three or four weeks old; at three or four months of age rickets is quite common.' Ritter has described extensive beading of the ribs in an infant of three weeks; Virchow, at five weeks of age. Moreover, he refers to the specimen of a rickety foetus in the Berlin museum. Hensch also records having seen two children, who were born 'with multiple incurvations and inflexions' of the bones, and with great softening of the entire skullcap. The writer has examined foetuses with unmistakable signs of rickets, and seen many cases, with well-marked symptoms, in infants of one month and upwards.

When it is considered that one of the earliest signs of rickets—enlargement of the epiphyses, according to some authorities the only pathognomonic sign—is not regarded as disease even by the profession, and that children so affected are not generally brought under treatment, it is not surprising that the published statistics show only about four per cent. of rickets in infants under and about three months of age. A recent analysis, by the writer, of one thousand consecutive cases gave the following particulars as to the asserted period of onset of rickets as usually understood. During—

			Per cent.
1st year	1st six months	202	20.2
	2nd six months	278	27.8
2nd year	3rd six months	238	23.8
	4th six months	144	14.4
3rd year	.	98	9.8
4th year	.	18	1.8
5th year	.	14	1.4
6th year	.	8	.8

The above figures show how great is the incidence of the disease during the earlier months of life, and they suggest a far-reaching and fairly uniform cause, such as congenital predisposition—heredity—to account for it.

Causes.—Enough has already been said to show how largely the constitutional element, in the writer's opinion, enters into the question of causation. Many authorities, on the contrary, regard *artificial feeding* as the chief, not to say sole, cause of rickets. This latter view, however, is very misleading, and leaves out of consideration those factors which are most potent; improper diet, however, is unquestionably a very powerful cause, and it is most likely to lead to rickets in children who are weakly and delicate from birth. That many children who are carefully suckled and brought up, suffer from the early phases of rickets, is a fact beyond dispute, and that many escape who are fed artificially, and indeed never thrive until so fed, is equally true; we must, therefore, be very chary in attributing rickets to errors in diet alone. Moreover, when several children in a family, one after the other, become rickety, the recognition that this depends on debility in the parents at once suggests prophylactic measures which will save much trouble, and greatly increase a future child's chances of recovery, or even its complete escape from the affection. The particular kind of food which is considered so detrimental to these children is that which contains *starch*—that is to say, all *farinaceous food*. It has been found experimentally, but on an extremely small scale, that neither the saliva nor the pancreatic or enteric juices of young infants (and of many animals) can digest starch—that is, convert it into glucose; hence the inference that the administration of starchy foods to infants is the efficient cause of rickets.

There can be no manner of doubt that many children, who are carefully suckled, get rickets even in its pronounced forms, and as little doubt that many children, who are artificially fed, escape. *Protracted suckling* is a not infrequent source of rickets, and is detrimental alike to mother and child. Indeed, the inducement in very many cases to begin artificial feeding is either (1) a deficiency in the maternal milk-supply, itself not seldom an indication of weakly health; or (2) because the child does not appear to thrive on the breast-milk—in other words, because the child already begins to manifest signs of a deficient assimilative power which is congenital with it. That rickets should begin, in the majority of these cases, so early after artificial feeding has been commenced, suggests a strong predisposition thereto; for it is hardly conceivable that such food as

is usually given to these infants—cow's milk or cooked flour in some shape or other—should be able to produce the universal and often profound changes, throughout the entire skeleton, which are found in infants of quite tender age. The amount of unaltered starch contained in a couple of nursery biscuits, or in a teaspoonful of baked flour, oatmeal, arrowroot, or cornflour, made into pap as given to children, is ridiculously small; and it is begging the question to attempt to explain such a widespread disorder on the hypothesis that this starch, one of the blandest and most universally distributed substances in nature, is the *fons et origo mali*! A large percentage of all the children in whom the osseous system is only, or chiefly, affected appear to be well nourished. 'Only thirty per cent. are really ill nourished' (Baxter). When it is remembered that animals fed on starchy diet die of inanition, it must be confessed that the starch theory of causation has yet to be proved. Of great moment, however, are the privation of fresh air and sunlight, and the influence of unhygienic surroundings during the earliest months of life. Ill-ventilated, overcrowded rooms, the re-breathing of expired air, want of cleanliness, are among the most efficient causes of rickets, even in cases where the predisposition thereto is not very marked.

It has been asserted that rickets is a worn-out syphilitic affection, but there is absolutely no truth in the statement. *Syphilis*—like *scrofula* or like *tuberculosis*—is a factor only so far as it deteriorates the general health of the parents, and so renders their offspring weakly and more receptive to any unhygienic influences to which they may be exposed. Thus, rickets is a disease not due to any one cause, but brought about by many acting in concert. It is largely the outcome of civilisation, which tends more and more to aggregate the population, and thereby to enforce that neglect of personal health in adults, which reproduces itself in the children (among other ways) as rickets. It must be borne in mind that other diatheses may be associated with rickets in the same subject. Thus, syphilis and rickets are constantly seen allied, as also rickets and tuberculosis and scrofula. The recognition of these facts is chiefly of interest in regard to treatment.

Pathological Anatomy.—Glisson and almost all subsequent authorities have drawn attention to the frequent association of pallor of skin, flabbiness of muscles, and special liability to pulmonary and to gastrointestinal catarrh with rickets of the bones,

as indicative of a general disease. Nevertheless, possibly because these lesions cannot be said to be special, pathological attention has been chiefly directed to the changes which occur in the skeleton; and yet, the former are by far the most frequent causes of death. When the osseous system is alone or chiefly affected, rickets seldom proves dangerous to life. Some or all of the following lesions may be found *post mortem*.

Viscera.—The *lungs* are often found emphysematous along their margins, with extensive patches of collapse in their interior; the bronchial tubes are full of frothy mucus, the presence of which, by impeding the entrance of air, leads to the collapse. On section, the adjoining lung-substance may or may not show bronchopneumonic changes. Not infrequently, on their surface may be seen signs of pressure from the depressed ribs: in a few cases, the beading of the ribs (generally most marked on the inner surface) produces a series of depressions, where they have pressed upon the lungs. The *stomach* is generally distended, pale, and bloodless; its mucous membrane is thin, soft, and readily breaks down under the finger; there are often local patches of congestion, with abraded surface in some cases, and tenacious mucus adhering to them. The *intestines* are also thinned and pale; they generally contain undigested food and flatus, as evidence of their want of power and tone; the solitary glands and Peyer's patches are often prominent and congested. The *liver* is sometimes enlarged, now and again the capsule is thick and whitish, and the substance firmer than usual; it is, however, more frequently fatty. The surface may be indented, where the beaded ribs have pressed upon it. The *spleen* is more frequently affected, being larger, heavier, and firmer than usual: this is apparently due to a greater or lesser degree of hyperplasia of the connective tissue. There is no reaction with iodine. Occasionally 'white patches' are found on its capsule. It must be stated, however, that changes in the abdominal organs are comparatively rare in the post-mortem room, and that children may suffer severely from rickets in whom no such or other visceral changes can be found.

Nervous system.—Although rickety children are unusually prone to nervous disorders, no pathological changes, except perhaps a slight increase in the cortical white matter in some cases, have as yet been discovered to account for them; in a few cases, the brain-substance is softer, and the ven-

tricles contain more fluid than normal; whether this is the result of a chronic change—part of a general catarrh—or is merely a compensatory transudation, it is impossible to say. There is no abnormal change in the *heart or vascular system*. 'White patches' are very common in children whose chests are deformed from rickets (Wilks); and appear due to friction against ribs projecting inwards: the 'chosen seat' (Jenner) is on the left ventricle, a little above its apex; the heart-muscle examined in a severe case, fatal from gastro-intestinal and pulmonary catarrh, showed no appreciable deviation from the normal. The writer, in conjunction with Mr. Shattock, examined the blood in nine living cases of rather severe rickets. In eight of the cases the number of the red corpuscles was in excess of the standard, in one case as much as '24; in the ninth case the number was reduced, as from 5 to 3; this blood, when drawn, looked very thin and 'hydræmic.' In most of the cases, the discs varied considerably in size and in shape, some being thorn-apple and some crenate; nor was anything, not found in healthy blood, observed. There were no nucleated discs. The granule-masses observed likewise presented nothing remarkable: the colourless corpuscles varied in size as in health; in one case only was there any excess. This negative result is not without interest, in a disease which affects the bones so profoundly, in view of the part which the marrow of bones is said to take in the formation of the blood. It is difficult to say how far any of the foregoing visceral lesions are specific, or whether they are merely accidental complications; their frequent association, however, suggests that they form an integral part of the disease. The occurrence or absence of one or other symptom is only in keeping with the clinical experience, that a general disease may occasionally show itself in one tissue more severely than in another.

Osseous system:—Although variable in amount and at different stages of the disorder, the condition of the bones, especially at the epiphyseal junctions, both to the naked eye and under the microscope, is the only one which is constantly present and at all pathognomonic of rickets. The *chemical composition* of the bones presents some striking deviations from the normal, the causation and significance of which, however, are differently interpreted by different authors; analyses of other tissues, with a view to establish whether they too present any variations from the normal,

will have to be made on a large scale, before it can be settled whether the changes found in rickety bones are the essence or the consequence of the disease. Friedleben's admirable researches show that the metabolic processes are particularly active in the osseous system of *all* infants during the second half-year of life; and that the chief chemical changes consist in an increase of the organic elements and a diminution of the earthy salts. This is just the period at which also some of the most characteristic of the so-called rickety changes occur, these latter changes being almost identical in kind, but greater in degree. According to this author's observations, the general chemical characters of rickety bones may be thus summarised: diminished quantity of the earthy salts, most marked when the disease is at its height, nearer the normal in the older bone layers, far below normal in the newly-formed (osteoid) parts, and in the latter an increase in the carbonic acid; little difference in the amount of fat, with the exception of the long bones, where it is increased in quantity by the marrow contained in the spongy parts, and in the enlarged medullary canals. The specific weight is lessened in proportion to the extent of the affection. The organic framework undergoes no obvious change, but the unossified cartilage contains more water. The grosser changes consist in peculiar and characteristic alterations in shape, and sometimes in consistence; all the bones, or only some few, may partake in the changes. The flat bones appear to suffer markedly.

In the *skull*, a condition termed *cranio-tabes*, first described by Elsässer, is frequently found to exist. The cranial vault becomes so thin and soft that it yields to the pressure of the finger; sometimes the bone is no thicker than parchment, and crackles when pressed upon. This condition may be confined to small areas, or involve the greater part of the parietal and upper part of the occipital bones, being generally found most marked in the posterior segment of the skull. In the healthy condition, even at birth, the cranial bones although very thin are nevertheless quite firm, and capable of resisting great pressure. See CRANIO-TABES. Elsässer distinguishes this softening from actual perforations (which are congenital defects), and from similar conditions associated with hydrocephalus, cephal-hæmatoma, inflammatory changes, and the like. Though found in other diseases, there can be no doubt that cranio-tabes is a sign of rickets *par excellence*: it is rarely found

after the twelfth, and occurs most frequently between the third and fifth months. In other cases, the cranial bones are much thickened owing to proliferation beneath the pericranium; unlike thickening of the long bones, which is more or less uniform, this occurs in patches or along the margins. The thickening may be very considerable and very localised: it differs from healthy bone in being soft and porous. At the sutures and fontanelles, which are the equivalents of the epiphyses, ossification goes on very irregularly; the sutures often become much thickened and sometimes project beyond the level of the adjoining bones. The interior of the skull-bones does not present any abnormal change; the dura mater is always very adherent.

The *scapulae* and *pelvis* are hypervascular, coarsely porous like pumice-stone on the surface, but possess a central, thin, firmer layer of normal bone; this outer deposit may have a distinct lamellar construction, and contains more marrow and less earthy salts than normal cancellated bone. Along their margins the bones are much thickened. The pelvic bones, from their position and the weight which is transmitted through them, often undergo important deformations, the permanent effects of which, in adult women, may interfere seriously with child-bearing. The *clavicles* become acutely bent (a condition which may be easily mistaken for fracture) just outside the attachment of the sterno-mastoid and pectoral muscles. The *ribs* often suffer greatly; normally they are more vascular than the other long bones, and are long in proportion to their size. Virchow teaches that the predisposition of certain bones to manifest rachitic changes stands in direct relation to their physiological use. It will be conceded that the ribs are constantly in use. There are two spots at which rickets manifests itself chiefly—viz. between the tubercle and the angle (which is often greatly thickened): at this spot in acute rickets infraction (spontaneous fracture) may not infrequently be found; secondly, at the anterior end. In cases of chest-deformity in infants, the tip of the rib is bent acutely on itself, the cartilage taking no part in many cases. So-called 'beading' of the ribs results from the proliferation which is going on at the costo-chondral junction; the expanded cartilage appears in some cases to fit on the rib like a cap, the enlargement being generally more marked on the inner than on the outer surface. The chest-deformities of later childhood are different, and follow no

regular type, being dependent on, and modified by, the effects of partial repair, of occupation, and of dress.

The *long bones* present certain pathological appearances on their surface, and along the epiphysial lines, which may be summed up as follows. The periosteum is everywhere thickened; it separates more readily than normal, owing to an unusual amount of newly formed hypervascular soft bone on the surface of the shaft; to its under surface, when so separated, will sometimes be found attached minute needle-like spicules of young bone, which have broken away from the shaft. On making a vertical section through the epiphysial junctions, the proliferative zone will be found increased from about half a line (as a normal) to as much as six lines or more in severe cases; and instead of being straight, it presents an irregular outline—that is to say, the cells are not arranged in rows as seen in normally ossifying hyaline cartilage, but are scattered irregularly over the whole ossifying area. The ossifying centre in the epiphyses is larger than usual, and is often of a *diffuse* character (Sutton). The changes consist in an increase, with deficient and irregular ossification, of the cell-proliferation, in the persistence of thickened cartilage-cells in these deficiently ossified layers, and in the formation of numerous small medullary spaces, even in the still unossified cartilage. The long bones undergo marked and quite characteristic deformities, which are usually attributed to a process of softening, and said to be part of the rickety process. On this point Glisson says: 'And first we flatly deny that the bones of children afflicted with this disease are more flexible or less stiff and friable than the bones of others.' The writer has osteotomised many deformed rickety bones in children from three to ten years of age, and has always found the bones remarkably hard; moreover, in the post-mortem room, he has never seen bones *presenting the ordinary rickety curves* in a soft stage, nor have any such specimens ever been demonstrated at the Pathological Society. If the bones were really softened, it seems hardly probable that the resulting deformities would be so uniform as they actually are in practice, while the fact of their spontaneously becoming straight without again softening, suggests some other explanation. The pathology of rickety bones varies of course with the age of the patient, and the stage at which they are examined; if the process is in full vigour, there will

be signs of increased activity, while later the appearance will be one of sclerosis and enlargement. Although spinal troubles are not infrequently complained of, there are no changes in the *vertebræ* which can be said to be characteristic: sometimes they are excessively spongioid, so that they may be cut with a knife (Barlow); the deformities in the vertebral column as a whole are chiefly due to a relaxed condition of the ligaments. Indeed, throughout the body, the *ligaments* suffer more than is generally recognised; they are nearly always more yielding, and as a consequence longer than in health.

Symptoms.—The onset of rickets may be so rapid as to deserve the term 'acute.' More commonly it is slow and gradual; indeed the earliest symptoms of the usual form generally escape observation, and rickets may long since have passed its initial stages, before it is noticed either by the child's parents or even by the doctor. It is very difficult to say what constitutes the first departure from the normal standard in many cases: a somewhat large head, with widely open fontanelles, profuse perspiration about the head, a dislike to sleep covered up, are common occurrences among well-fed, firm-fleshed infants at the breast, and yet the foregoing are signs *par excellence* of the rickety disorder. Presently, the epiphyses, markedly those of the lower end of the radius, begin to enlarge, and in time the child becomes 'double-jointed.' In many cases Elsässer's soft patches on the skull-cap (craniotabes) will be among the earliest symptoms; they are especially frequent in babies with thin, lank hair. In other cases the chest becomes deformed—prominent along the sternum, and sunken in along the costo-chondral junctions; the tips of the ribs will be found 'beaded;' dentition is irregular rather than late, as generally stated, or both; sometimes the spine grows out, and the child cannot sit up, or is altogether backward for its age. The ligaments may be loose, and the knees or ankles, or both, 'give in' whenever the child attempts to stand or walk. In the earlier months of life, rickety children are especially liable to catarrh of the bronchial and gastro-intestinal tracts; hence bronchitis, with its sequel of collapse, is common; or a weak and easily disturbed digestion, indicated by vomiting, diarrhoea, and offensive stools, will be the sign which betrays the disease. 'Rickets is not a cause of pyrexia; if the temperature rise above the normal level, a complication may at once be suspected' (Eustace Smith).

Convulsive disorders are a frequent and often the only morbid manifestation of the rickety diathesis; they are most common in children under two years of age, and belong to the earlier stages of rickets. These convulsions are usually said to be reflex; laryngismus stridulus and carpo-pedal contractions are practically confined to the subjects of rickets. Tetany also is closely associated with rickets (Abercrombie), and some cases of strabismus are due to the same cause; indeed, not less than two-thirds of all the convulsive attacks to which children are liable will be found due to, or associated with, rickets. In a few cases there is great tenderness; the child objects to being handled, and cries when it is raised up. Such are the clinical signs of rickets, varying a little with the period of life when the diathesis begins to make itself prominent, and with the organs or system chiefly or first attacked. The antecedents, or some of them, to which reference has already been made, on inquiry will almost certainly be made out. Occasionally, fidgetiness and 'growing-pains' point to the onset of rickets, or the bone-deformities come on more or less rapidly without an apparent cause.

As regards *individual symptoms*, it may be said that the *facies* is almost characteristic. There is a disproportion in size between it and the head; the latter tends to become square; the frontal eminences are large and prominent, and the sutures thickened and often distinctly elevated; on palpating the head it feels hard and lumpy. The teeth are said to be less durable than in healthy children, and the alveolar processes altered in form; but these symptoms are not very reliable or well-defined. There is a great tendency to sweat profusely about the head, which is very suggestive, and, as if they felt hot, these children throw off the bedclothes at night and prefer to sleep uncovered. The abdomen is generally prominent; the chest is nearly always flattened at the lower lateral parts, and more so on the left than on the right side; at the junctions of the ribs with their cartilages there is often 'beading.' The spinal column may be affected or not; owing to flabby muscles and loose ligaments, and sometimes to the weight of a larger head than normal, the child cannot sit up firmly; the spine then forms a curve, either backwards or laterally—the direction being determined by the posture which the child most frequently maintains. The deformities of the long bones may be said to differ within rather narrow limits; they

are very similar one to another, and so generally symmetrical that an affection of one side alone would bring the diagnosis into doubt. The tibiae, of all the bones, are perhaps the most frequently affected; the 'seat of election' is in the lower third, and the common curve is outwards and forwards. In a few cases the stress falls on the crest of the shin, which becomes prominent and sharp and curved. The fibula doubtless participates in these deformities, but from its deep position they are less manifest. The femur is less frequently affected; the commonest curve is in the upper third, and in direction outwards and forwards; in the lower third it curves inwards, and so contributes to the formation of knock-knee. The bones of the arms suffer markedly in a few cases, the humerus suffering more frequently than the bones of the forearm. The ligaments are nearly always flaccid, temporary knock-knees and flat-foot resulting in many cases. Rickety children generally grow slowly, they are large-boned, and their stature is often stunted.

Prognosis.—The prognosis in individual cases will vary with the child's age, the stage of the disease, and the absence or presence of complications. In uncomplicated cases a good prognosis can be given with confidence. By far the commonest cause of death is pulmonary or gastro-intestinal catarrh. The tendency to these diseases lessens as age advances, but they are very fatal to young children. A few children die of the nervous complications, either of convulsions or of laryngismus, especially when their origin in rickets is not recognised. As regards the deformities, it may be said that in ninety per cent. all traces disappear in process of time; in a few, permanent deformity of the bones remains. The thorax, especially, never quite regains its normal shape, if deformity has once been marked; and the same may be said of the skull. But in all other respects the children grow up strong and well, though it may be that their stature is somewhat dwarfed.

Treatment.—A consideration of the causes, just enumerated, which combine to produce rickets will suggest prophylactic measures of great value; for, whatever strengthens a woman's health strengthens that of the child she may be carrying or suckling, and whatever tends to deteriorate the mother's health, either before or after parturition, predisposes her child to rickets. The causes, among the rich late hours and various social exactions, among the poor the debilitating influences of poverty, must

be removed as far as possible, and a rational mode of living be insisted upon by medical men for all pregnant and suckling women, rich and poor alike. A large proportion of infantile mortality is directly due to causes acting on the children antecedently to their birth, combined with unsuitable food and attention subsequently. There can be little doubt that the best diet for an infant is its mother's milk, and any conditions or surroundings which tend to lessen either the quantity or the quality must be avoided. The cases in which mothers' milk is likely to be injurious to their own infants are extremely few; the writer doubts very much whether a mother can convey to her own child through the milk any constitutional taint or weakness, which it has not already inherited *in utero*. The excuses for not suckling children are often really trivial, and should be discountenanced by the medical attendant; the health of the mother is improved and her tendency to disease in the breast lessened by suckling, the temporary inconvenience being more than neutralised by the advantages which the proper carrying out of the physiological functions in the breast, entailed by child-bearing, brings with it.

Rickets is essentially curable, and cod-liver oil is the remedy for all forms of the disease. It should be given in doses of one teaspoonful or less, alone, or combined with either steel-wine or lime-water. Very few children fail to become reconciled to it, with perseverance on the part of their parents; when given alone, a teaspoonful of orange wine, or black coffee, or milk, forms an excellent vehicle, and a nicely flavoured lozenge removes the taste afterwards. Its use must be continued for some months, with short intermissions, and it is most useful when given shortly after food for it is then mixed, digested, and absorbed along with the food. Judicious management of individual symptoms is of course necessary. If an infant is suffering from the effects of an improper diet, improvement cannot be expected so long as this diet is continued. On the other hand, let it be ascertained whether *too much* food is not being given, and *too often*, before it is said to be improper. In a few cases the mother's milk distinctly disagrees: this may be a radical fault, or depend upon fleeting conditions of health easily remedied. In the former case, some other food must be tried, and given in addition to, or substituted for, the milk. *Fresh milk* (either cow's, goat's, or ass's), suitably diluted according to the age of the child, should

always form a part of the diet; it may be alternated with one or other of the many artificial (malTED) foods now in vogue, that one being finally selected on which the child thrives best.

There must be no hard and fast routine diet for all children; what agrees with one may disagree with another, while a little variety is beneficial to all. But in all cases, some *fresh* food—as opposed to the *prepared* foods—must be given. It is not an uncommon error to give the food too strong, and especially so in the case of weakly infants, who do not thrive; the more feeble an infant, the less can it digest complex or strong food; even cows' milk must be diluted more than usual; it may even be well to partially digest it by means of pancreatine before giving it. A fertile source of mischief is an unclean feeding bottle. Even with the best will it is not easy to keep the bottle and the tube thoroughly sweet; under these circumstances it is well to get new tubes and new teats at short intervals. A little pounded raw, lean meat is of great service in many cases, and can never do harm; from one quarter to half an ounce once or twice a day may be given. Fresh fruits, fruit-juice, part of an orange, or a piece of lemon (well sugared) to suck, a roasted apple or pear free from skin and husks, are valuable aids to digestion, even for quite young infants. For older children, green vegetables, lettuce, cress, celery, tender and fresh from the garden, should be given. A pinch of salt with the food must not be forgotten. It is well to avoid tea, coffee, and stimulants.

Next in importance to the food are fresh air and light in the nursery; for the latter a south or south-west aspect is the best; too high a temperature must be avoided, and the air constantly changed. Bathing is of great value to rickety children: with salt water, if it can be procured, if not, with sea-salt dissolved in the bath water as the next best substitute. The whole body should be well sluiced with a bath sponge for a minute or two, and then be systematically rubbed and shampooed; for an infant, and in winter for older children, the bath should be comfortably warm (90° to 95°), in summer it may be nearly cold; all chilling is to be avoided, and individual idiosyncrasies as to heat and cold carefully respected. When children are ill, and suffering from catarrh, the regular bath may be suspended for a time. Outdoor exercise should be taken every day. Flannel should be worn next the skin; it should reach well up to the neck, and as far down as the knees, in order to

protect without constricting the chest and the abdomen; for sleeping, a 'combination' dress is best; the children cannot then get entirely uncovered, as they are apt to do in the ordinary night-dress. The severer lung and intestinal complications must be treated on the principles laid down in the medical text-books; but it is well to say that cod-liver oil often acts like a charm, even in this stage of rickets.

Deformities, unless very marked, may be left alone; the crooked bones tend to straighten spontaneously under the influence of general remedies. In the case of severe deformities, light splints may be worn. The writer never uses splints which pass beyond the feet; if children are so splinted that they cannot walk, they shuffle about the ground, and take more harm from this mode of progression, and the dangers incidental to it, than the wearing of such splints compensates for. If the deformities resist treatment, or continue to progress notwithstanding, and become really severe, then osteotomy may be resorted to. But patience is the great requisite, as time and cod-liver oil are the remedies for such cases. When cod-liver oil causes diarrhoea, a minim or more of tincture of opium may be combined with each dose until the oil is tolerated. In warm weather, also, the opium sometimes proves a valuable adjunct, and permits the administration of the oil to be continued, when otherwise it could not be borne. See BOW-LEG; GENU VALGUM; OSTEOTOMY.

ACUTE RICKETS.—This term has been used by different authors in rather different senses. By some (Jenner, Ritter, Rehn) it has been used to denote an unusually rapid onset of the ordinary form of rickets; by others (Stiebel, Mauthner, Senator) to signify a very severe form of the disease with an acute onset. By Möller it is used to describe what he regards as a disease distinct from rickets, in which subperiosteal hæmorrhages or effusions are a characteristic symptom; by Bohn as an inflammation of bone in consequence of its over-rapid formation; while Henoch hardly believes in the existence of such a condition, chiefly because he has never seen a case in his own practice.

There is no doubt that rickets—like many other diseases—may have a very rapid onset, and occasionally, also, assume a very severe form, for which cases the term 'acute rickets' is very appropriate. Dr. Mauthner of Vienna, about thirty years ago, recorded some of the first and best cases. Dr. Möller of Königsberg also reported three

cases of 'acute rickets' in artificially-fed children, with enlargement of the joint-ends of several bones, occurring simultaneously or in rapid succession, and accompanied with such considerable persistent pain (which was aggravated by handling the children) that osteitis was suspected. There were no bendings in the bones, but in two subsequent cases, he found, *post mortem*, subperiosteal effusions of blood, with spongy (scurvy) gums and sugillations in one of the cases. Later again, Dr. Rehn of Frankfort described a series of cases of 'infantile osteomalacia,' which evidently belong to the same class as the foregoing. Dr. Thomas Barlow regards the term 'acute rickets' as inappropriate, and suggests that these cases are 'probably a combination of scurvy and rickets, the scurvy being an essential, and the rickets a variable element.'

The clinical history of these cases differs widely. The disease is not confined to the poor: it may occur up to three years of age, but is most common under or at about eighteen months; one of the earlier symptoms is pain, which is aggravated when the child is handled. Most of the cases have been in ill-cared-for, artificially-fed children of either sex, and without regard to season. The writer recently saw a well-cared-for infant with this condition highly marked, which had supervened in the middle of summer at Brighton. The duration rarely exceeds two or three months. In some, treatment has appeared of little avail, in others a cure has been effected in a week or two; while other cases have gradually, and for the most part slowly, recovered spontaneously. The general cachexia has not been at all profound, and, when death has occurred, it has been due chiefly to pulmonary catarrh, and not to the local lesions. In a few of the cases the gums are reported to have been spongy as in scurvy, and in some of the cases subperiosteal hæmorrhage has been found. The bones undergo strange deformities, quite unlike those of ordinary rickets; instead of being curved, they assume sharp angular flexions, termed 'infractures,' the epiphysal changes being usually ill-marked. The writer has examined three such cases *post mortem*, and feels no doubt as to the rickety nature of the lesion. Apart from the pathological appearances, there are the social surroundings which usually obtain in the more common form of rickets; the variation from the ordinary type is easily explained by the personal element present in all kinds of disease, and by the age of the patients when attacked. As regards the subperi-

osteal hæmorrhage, it is probably traumatic, and brought about by the rough handling to which many of the children are subjected before coming under treatment.

The appearance of the hæmorrhage early in the course of the disease, the absence of profound cachexia and of putrescence, and of stomatitis in many of the cases, distinguish this lesion from true scurvy. The latter disease, when it occurs in children, presents the same features as in adults, and it is brought about by the same causes—long privation of fresh, and the ingestion of improper, food *during cold damp weather*. It is quite exceptional for adults exposed to these conditions to escape scurvy; on the other hand, the cases of so-called 'infantile scurvy' are extremely uncommon, notwithstanding that an immense number of infants are being brought up on what Mr. Herbert Page describes as 'scurvy diet.'

Treatment.—The affected bones must be carefully protected from injury by appropriate splints; the less the limbs are handled the better. A child should be kept in the prone position, and be moved as little as possible. Place the child on a large soft pillow; instead of the usual dress, cover it with soft warm flannel, and in this way dressing and undressing will be avoided. Opiates may be given to relieve pain, if acute. General treatment must be on the lines already laid down—fresh food and fresh fruits being of great value.

FETAL RICKETS.—This term is now reserved for a peculiar form of disease in fetuses, which consists in profound changes in the skeleton having a superficial resemblance to rickets, but which are frequently associated with absence of the thyroid gland, or with premature synostosis of the basi-occipital and basi-sphenoid, or sometimes with both. This condition is also and more appropriately called 'fœtal cretinism;' the severer forms of the disease appear to be incompatible with life, for the cases described have been still-born fetuses of varying ages. A few isolated cases had been previously recorded, but Virchow was the first to describe the condition at all accurately. Many cases have since been reported. The extreme shortness of the diaphyses, relatively to the large size of the epiphyses, is the most marked pathological feature; microscopically examined, there is very deficient ossification at the epiphysal line, with intrusion of fibrous tissue from the periosteum, which Mr. Bowlby regards as the cause of the shortening and of the changes in the cartilage. The premature synostosis at

the base of the cranium has been found in several cases; but it is not invariable. Virchow regarded this as the distinct feature of this condition, and the cause probably of the arrested brain-growth. As for the thyroid gland, it has been found absent in some cases and present in others; the part which its absence or presence plays in the causation of this form of cretinism cannot therefore be estimated. A goitre has been found in some cases, and in a few others peculiar masses of fat above the clavicles are met with. Children with the less severe forms of the disease not only survive their birth, but may live for many years. Not infrequently one of the earliest signs of their cretinoid condition is hypertrophy of the tongue, which projects beyond the lips. Then the child gradually assumes the look of hebétude which is characteristic of the disease; intellectual and bodily development are greatly impeded, so that they still appear young children even at sixteen or eighteen years of age.

Authorities agree in regarding this condition as entirely distinct from ordinary rickets. It would be well, therefore, to discontinue the term 'fœtal rickets' and substitute 'fœtal cretinism.' Dr. Barlow points out how the disease attacks the cartilage bones only, the bones which are formed in membrane being all well developed. The enlargement of the *whole* epiphysis; the thickening of the shafts of the long bones, which are hard and compact; and the absence of rarefaction in the medullary part of the bones distinguish the condition from true rickets.

LATE RICKETS.—Cases of rickets commencing at eight, nine, or ten years of age are by no means rare, though exceptional. Glisson refers to a case of rickets in a man twenty years of age. In the Middlesex Hospital Museum are casts of rickety deformities of the legs in a young man aged twenty, which appeared after an operation for genu valgum. The writer has seen two cases of typical rickety deformity in subjects fourteen and sixteen years of age, which were said to have 'come on quite lately.' Besides these, several anomalous cases of bone-disease in young adults have recently been put on record, in which the epiphyses have shown rickety enlargement, while the shafts have presented other changes less easy to define. By some, the condition is regarded as a juvenile osteomalacia, and an attempt has been made to trace a connection between this latter disease and rickets; the differences between extreme cases are quite obvious, while intermediate ones—that is to

say, cases of late rickets and of early osteomalacia—are said to merge one into the other.

The writer is not at all inclined to acquiesce in this view. It is obviously unscientific to argue, because the ultimate outcome of two processes is more or less alike, that, therefore, they are identical. Pathological processes must rather be interpreted in the light of the clinical history. The rickets of infancy and childhood is a general and not a local disease, and death never takes place in consequence of the local bone-manifestations. Osteomalacia, on the other hand, is a disease of adult life, and of bones which were once absolutely healthy. The disease, unlike rickets, is local in its commencement, and remains so for years in some cases, while steadily progressing nevertheless; all the other functions of the body go on unhindered. Women, whom the disease chiefly affects, bear children; their intellectual power is unabated, and all the other functions may go on normally. Osteomalacia is a degeneration, a softening of healthy bones; rickets is an arrested and deficient development, not of the bones only, but a condition in which all the tissues participate. In a few exceptional cases, rickets may come on later in life than usual, just as osteomalacia may occur a little earlier. Rickets, however, is a very uniform disease, especially as it affects the bones, and the resulting deformities resemble each other as closely as the manifestations of the most specific diseases; the same may be said of the osteomalacia of women. The intermediate cases, which differ immensely among themselves, must, for the present, be relegated to a separate category. The causes which lead to this condition are not known. There can, however, be little doubt that late rickets is the expression of debilitating influences, of one kind or another, acting on the organism at large.

RELAPSING RICKETS.—A term applied to those cases in which the disease, having been apparently arrested for a year or two, again becomes active. Such cases are by no means uncommon when looked for. In the writer's opinion many cases of 'late rickets' may be accounted for on this supposition. Intervals of a year or eighteen months or even longer occur, during which no further signs of rickets manifest themselves. Then, owing either to want of care, to untoward surroundings of various kinds, to acute illness, or to change of air from a dry open country to a cold, moist, overcrowded town, sometimes without appreci-

able cause, a child's health gives way, and rickety (generally bone) disorder again shows itself. The symptoms vary with the age of the patients, and with their early bringing up. Knock-knees and other deformities arising from loose ligaments, such as spinal curvature and flat-foot, generally belong to this category. The treatment of these conditions must be conducted on the principles already laid down.

ROBERT WILLIAM PARKER.

RIDER'S BONE or RIDER'S STRAIN.—In persons who ride much, a hard lump sometimes forms on the inner side of the thigh, near the pubes. It is due to an ossification of the tendon of the adductor longus or gracilis, or to an exostosis growing from the pubes, and extending along the adductor tendon. There is a history of a severe strain, which has ruptured some muscular or tendinous fibres, or torn the tendon partially from its insertion. The subsequent irritation of the saddle causes the growth of bone. No treatment is of any avail, but this does not matter much, seeing that the swelling is more troublesome from its size and situation than from any pain it causes, and is very rarely seen in this country.

A. G. MILLER.

RIGOR is the name given to an aggregation of phenomena, all referable to the central nervous system, which, while frequently heralding the appearance of more unequivocal signs of serious mischief, are not necessarily developed in proportion to the gravity of the illness.

Symptomatology.—A patient, the subject of a severe rigor, lies shaking from head to foot, with tremors (frequently amounting to violent clonic spasms) affecting every muscle; consequently, the teeth chatter, the face twitches, the eyelids and corners of the mouth making opening and shutting movements; the head, supported on each side by the pillow, rarely moves much, the body often rolls in the bed, from the jerking impulses given to it by the violent contractions of the muscles which pass from the trunk to the limb-bones. Indeed, the bed is very frequently shaken by the violence of the tremor.

All this time, although the temperature is rising and may be up to 104° F., the patient complains very much of feeling intensely cold, and covers himself with every possible wrap, or gets close to the fire. There are no symptoms to indicate any active change occurring in the highest

nerve-centres, for the patient is always perfectly conscious, and sometimes his special senses appear to be rendered more acute. The clonic spasms, though varying considerably in force, exhibit a fairly constant rhythm, the rate of which appears to be frequently the same as that of ankle clonus, but sometimes of only half that rate.

In addition to the above-mentioned motor symptoms, others are often seen which indicate disturbance of centres for functions besides movement. Thus, vasomotor changes are observable in the shape of a leaden colour of the skin, which is dry and rough. Other centres in the medulla oblongata are also disturbed, so that the patient may be nauseated or actually vomit, the respirations may be slowed, and the action of the heart enfeebled and quickened. As indicated above, the temperature is usually rising at the time when the rigor occurs, for a rigor customarily occurs when the temperature has gained from one-half to two-thirds its maximum height.

Etiology and Causation.—There is no striking peculiarity about the array of symptoms, familiarly termed a rigor, which furnishes us with the slightest clue to its causation in fully ninety per cent. of all cases; for while we know so little respecting the origin and causation of acute specific fevers, it is clear we shall remain ignorant of that pathological state of the central nervous system which produces the rigor heralding the onset of the disease.

There only remains to us the suggestive fact of rigors being sometimes produced by traumatic influences. It is well known that, after sudden dilatation of the urethra by a catheter, there frequently follows a violent rigor, accompanied by a rise of temperature. See URETHRAL FEVER. In such a case, we have simply the irritation of peripheral nerves causing a profound disturbance of the spinal cord and medulla oblongata. Of the accuracy of this pathology there can be very little doubt, but it would be very improper to apply it to explain the occurrence of rigors in pyæmia, ague, &c., until the causes of those diseases are thoroughly known. That rigors are of central origin is obvious, and the only question is the mode of irritation which the nerve-centres suffer.

Treatment.—The treatment of a rigor has almost always been the simple plan of stimulation and heat, in the shape of doses of brandy and hot water, extra blankets, and hot bottles. If it were not for the

concomitant disturbance of the heart, &c., rigors would require but little attention. It has been shown, experimentally, that any drug which narcotises the nerve-centres exerts thereby a powerful preventive effect on rigors and pyrexia. Thus, Dr. Johnson proved that chloroform, &c., would arrest a rigor, and it is well known that morphia and quinine will prevent and arrest rigors due to catheterism, and possibly those occurring in pyæmia. But, for practical purposes, it will be found best to administer a hypodermic injection of morphia (gr. $\frac{1}{4}$ to gr. $\frac{1}{2}$), to cover the patient with blankets, to warm the surface of the body with heated air or hot-water bottles, and to supply him freely with hot alcoholic drinks. For the prevention of rigors, see URETHRAL FEVER.

Prognosis.—As far as the rigor itself is concerned the prognosis is always very favourable, however alarmingly violent the spasms may be; but, as indicating other mischief, the occurrence of a rigor will always render the prognosis very serious, and, if there is concurrently suppression of urine, &c., it will make it practically hopeless.

VICTOR HORSLEY.

RINGWORM. See *TINEA TONSURANS*.

RISUS SARDONICUS. See *TETANUS*.

RODENT ULCER. See *CARCINOMA*; *ULCERS*.

ROUGE'S OPERATION may be required for the removal of necrosed or carious bone when, either from the size of the sequestrum or from the situation of the disease, this cannot be effected through the nostrils. It may also be resorted to for removing certain forms of nasal and naso-pharyngeal polypi, when more room is required than can be obtained through the natural passages, and when it is especially desired that no external scar should remain. Further,

it is sometimes useful for allowing the introduction of the finger into the nasal chambers, for the purpose of thoroughly exploring these parts in cases of long-standing disease attended with foetor, where the presence of diseased bone is suspected but cannot be detected by the mirror or probe.

The operation is performed as follows:—The upper lip having been seized on each side near the corner of the mouth and turned upwards, an incision should be made, reaching from the first pre-molar tooth on one side to that on the other, through the mucous membrane at its reflection from the lips to the gums. The tissues intervening between the mouth and the nasal cavities should next be rapidly divided, and the cartilaginous septum detached with the bistoury from its insertion into the anterior nasal spine. This is often sufficient to allow of the introduction of the finger and the exploration of the nasal cavities; but if more space is required, the lateral cartilages should be detached from the maxillary bones with the scissors, when the nose, thus completely freed, can, especially when the septum has been partially destroyed by the disease, be turned upwards towards the forehead, widely exposing the orifice of the nasal chambers. Where the septum is intact, it will generally require further separation from the maxillary crest by the scissors. The removal of the dead bone or growth, or the exploration of the nasal cavities, having been effected, the lip and nose should be accurately replaced, care being taken that the base of the septum is placed in exact contact with, and is supported by, the nasal spine. No sutures are necessary; little or no swelling of the lip follows the operation; there is, as a rule, no constitutional disturbance, and the parts are usually soundly healed in a few days. W. J. WALSHAM.

RUPIA. See *SYPHILIS*.

S

SABRE and BAYONET WOUNDS. Sabre wounds chiefly affect the head and upper extremities, bayonet wounds are chiefly on the lower extremities. Neither are very fatal, the bayonet wound being rather more so than the sabre.

Sabre wounds.—The sharper the weapon, the more the injury inflicted will resemble an incised wound. When the sabre is very sharp it may cut a portion of

tissue completely away. The blunter it is the more irregular and contused the wound will be, and the deeper the weapon penetrates the more it will gape. When the cutting edge strikes the surface perpendicularly, a straight gaping wound will be inflicted; if obliquely, one margin may be concave, the other convex, or the wound may be more or less flap-shaped, especially on the face and skull. When the

bone is implicated by a blunt weapon, it may be bruised or fractured; if sharp, it will be incised or a portion more or less completely detached. The bleeding is not great unless a considerable vessel be injured or the weapon very sharp. If the large veins in the neck are wounded, sudden death may take place from entrance of air. The amount of pain will depend on the nervous supply to the injured part. When large nerve-trunks are divided, there will be interference with sensation and movement in the parts which they supply.

A blow of a blunt sabre on the head will often produce injury of the brain-convolutions of the opposite side, or fracture the skull; especially will the internal table be injured and extensive fissuring produced. The skull and face are most often wounded; next to these the hands and arms almost as frequently. These wounds are much rarer on the chest and back, and very infrequent in the abdomen and lower extremities.

Punctured wounds are caused in time of war by bayonet, lance, and sabre. They are by no means of frequent occurrence, and as seen in the hospitals are not of great severity. There is no accurate information as to the number which prove fatal on the field. They are chiefly met with in the breast, abdomen, and upper extremities; less frequently on the head, face, and lower extremities. They are usually long blind canals with a triangular or quadrangular wound in the skin, according to the form of weapon. The bone may be perforated or fractured. They often contain foreign bodies or a portion of the weapon which has broken off. The vessels often escape in a remarkable manner, and a comparatively small wound in the vessel may sometimes close after the primary hæmorrhage has ceased, frequently to be followed by a traumatic aneurism. When the wound implicates both the large artery and vein, aneurismal varix may follow; nerves may be punctured or divided, and tetanus is then comparatively common. These wounds often penetrate cavities and injure the contained viscera. Cut and thrust wounds may heal by first intention without suppuration, or their progress may be modified by all the circumstances which influence the course of gunshot injuries.

The prognosis will depend on the depth and extent to which they implicate important cavities or organs.

The treatment consists in the arrest of hæmorrhage, the extraction of foreign bodies, and antiseptic purification.

WILLIAM MACCORMAC.

SACRO-ILIAC JOINT, Disease of the.—This joint is not often the seat of primary disease, but is more usually affected secondarily by the spreading of caries from the adjacent surface of the ilium or sacrum. The disease is generally of constitutional origin, and is for this reason, as well as because of its anatomical relation to the spine and pelvis, to be looked upon as an affection of much gravity. It may, however, originate in injury, and occasionally follows parturition.

The earliest *symptoms* of sacro-iliac disease are usually pain and slight lameness. The pain may be felt in the situation of the joint, or in the course of some of the neighbouring nerves. Most often it is felt along the great sciatic nerve and its branches, so that, in the early stage, sacro-iliac disease is apt to be mistaken for sciatica. Not uncommonly also the pain is referred, as in hip-disease, to the hip and knee, in consequence of irritation of the obturator nerve. The pain, wherever it may be, is increased by movement, and whenever the weight of the body is transmitted through the pelvis, as in sitting or standing; so also, an attempt to lift a heavy weight from the ground will generally elicit or aggravate pain. On the other hand, relief is given by the recumbent posture. The lameness at first is chiefly due to slight involuntary elevation of the pelvis on the affected side. Sometimes there is flexion of the thigh, in consequence of irritation of the psoas muscle. As the disease progresses, tenderness will be felt on pressure over the joint; pain will be produced by pressing together the two iliac bones; the gluteal muscles will become wasted; and suppuration will occur. When matter forms, it will most commonly present over the back of the joint, but it may also make its way to the groin after the manner of a psoas abscess, or outwards along the crest of the ilium, or forwards towards the rectum, from which it may be felt by the finger.

Diagnosis.—It will be observed that, in many respects, the symptoms described closely resemble those of disease of the spine or hip, and in the commencement of sacro-iliac disease a careful examination is needful to distinguish it from those affections. From disease of the spine, it will differ chiefly in that the symptoms are referable to one side only of the body; and that if the pelvis is fixed, flexion of the vertebral column is not restricted or painful. From hip-disease, it may be distinguished by the free mobility of the femur independently of the pelvis.

Pathology.—The disease usually begins either in the bone or periosteum, though possibly, in some instances, the starting-point is an extravasation of blood into the tissue about the joint, the result of direct injury. In advanced cases the articular surface is found carious, the fibro-cartilage loose, the ligaments softened, and the joint surrounded by extensive suppuration.

The *prognosis* will depend chiefly on whether the disease is of constitutional or local origin, and upon the extent to which the mischief has progressed before treatment is commenced. In the scrofulous or phthisical the affection is always a grave one, as it must also be considered whenever suppuration has occurred.

In the *treatment*, the first essential is absolute and prolonged rest in the recumbent position. The immobility of the joint may be aided, moreover, by surrounding the pelvis with a well-moulded leather splint or a padded pelvic girdle. The only local application of any use, is the light and repeated application of the actual cautery over the back of the joint. This is, of course, only serviceable during the early stage of the disease and before suppuration has been reached; but at this period it sometimes gives remarkable relief to the pain, especially to that along the course of the sciatic nerve. Blisters and other milder counter-irritants have no effect but that of adding to the discomfort of the patient.

When abscess has formed it is generally best to open and drain it, with antiseptic precautions. If not opened, abscesses are prone to attain a large size, and to burrow in a manner which makes it subsequently very difficult to drain them efficiently; if aspirated they usually rapidly refill. No doubt cases have occurred in which such abscesses have undergone so-called absorption—that is to say, they have dried up; but this implies a residuum of caseous material which may be the source of future dangers. In phthisical cases it is, perhaps, best not to interfere with the abscess unless it is distressing the patient.

When the disease becomes arrested, and only a sinus remains, it may be useful to explore the part to ascertain if there be any removable dead bone, or for the purpose of scraping away the granulations which supply the pus; but these measures should not be resorted to till every opportunity has been given for natural repair. Besides the local measures which have been indicated, the constitutional condition of the patient should receive attention. As a long period of recumbency will be necessary, it

is important to secure the best possible environment; while, at the same time, nutrition should be aided by good food, cod-liver oil, or other suitable tonics.

J. WARRINGTON HAWARD.

SACRUM, Fracture of the. See PELVIS, Injuries of the.

SALIVARY CALCULI are concretions of earthy salts deposited by the saliva, and consist of phosphate and carbonate of lime, with a little magnesia, chloride of sodium, and some organic matter. They are usually of elongated form and small size, but may attain very large dimensions; thus, Albert has seen one removed from Wharton's duct which measured over an inch and a half in length, and was as thick as the little finger; and he mentions another as large as a hen's egg, taken from the duct of the parotid. They are most frequently met with in connection with the duct of the sub-maxillary gland, but the ducts of Stenson, Rivini, and Bartholin may also be involved. The obstruction of the tube is rarely complete.

They may appear at any age, and are said to be more common in men than in women. Their development is seldom explicable, but in a few cases the nucleus of the stone has been found to consist of a grass seed or some other foreign substance.

The *symptoms* are usually slight. The patient complains of a sense of discomfort and tension in the situation of the impacted calculus. The gland, from retention of secretion, undergoes painless swelling, which continues until the imprisoned fluid forces a way past the foreign body; the engorgement then rapidly subsides, to be followed by a new accumulation, and a characteristic alternation of tumefaction and collapse becomes established. Cystic dilatation of the tube behind the obstruction is very rare.

The *diagnosis* is effected by careful palpation along the course of the ducts, aided, if necessary, by the introduction of a fine metallic probe.

The calculus may be removed through an incision made into the distended portion of the duct, or the tube may be laid open from its orifice as far as the obstruction. The continuous flow of saliva prevents any tendency to stricture after the operation.

WILLIAM ANDERSON.

SALIVARY FISTULA.—A sinus opening upon the outer surface of the cheek, and communicating with the duct of the parotid gland.

Such sinuses have origin either in wounds of the duct, or in abscess which has burst externally, or in obstruction of the buccal end of the duct, causing its distension and subsequent opening on to the surface of the cheek. Much discomfort is produced by the escape of the saliva upon the cheek; the flow of the secretion being of course increased during mastication.

Treatment.—Fistulæ of recent formation may sometimes be made to heal, if the buccal orifice of the duct be quite free, by covering the opening on the cheek with collodion, a layer of which must be reapplied from time to time, so as to prevent the escape of any saliva; fluid food only being taken during the treatment.

If this does not suffice, the edges of the opening should be pared, and then transfixed with a fine needle, over which a figure-of-eight ligature is to be tied, so as to bring them into accurate apposition. The needle is withdrawn at the end of forty-eight hours, and the wound covered with collodion. Or the orifice of the sinus may be first cauterised with a hot needle and then similarly covered. If the buccal opening is contracted or closed, this must be reopened by passing a fine probe through it; or, if it cannot be found, a probe must be passed along the duct and into the mouth as nearly as possible to the natural orifice (near the second upper molar tooth). Then the duct must be kept open by passing a flexible probe or bougie along it from the mouth, past the fistula, and as far as the gland. This is retained by curving the end which projects from the mouth round the angle of the cheek, and fastening it there by plaster. The fistulous opening is kept covered with collodion, and mastication avoided. J. WARRINGTON HAWARD.

SALIVATION. See *Mercurial Stomatitis* under STOMATITIS.

SALTER'S SWING CRADLES. See CRADLES.

SANDBAGS are useful for steadying broken limbs, either alone or with splints; and in combination with a drawsheet laid over the chest and abdomen and under the sandbag which is placed along each side of the patient, they efficiently overcome the aching of the spine which occurs in the extension treatment of hip-joint disease. The bags should be made of some fine-textured material, such as bed-ticking, and should be only about two-thirds filled with sand, which must be as fine as possible and thoroughly dried.

SAPRÆMIA is a term which may, perhaps, etymologically include more than it is now generally understood to mean; but, expressing as it does very succinctly the condition in which there is present, circulating in the blood of a patient, one of the alkaloidal products of decomposition (*see* SEPSIN), a condition which is otherwise known as septic intoxication—a cumbersome title—or as septic poisoning, which is much too vague, it at least has the merit of brevity coupled with sufficient accuracy to commend it for permanent adoption. By the term *sapræmia* we understand the condition which is sometimes very wrongly called traumatic fever, or, what is worse, simple traumatic fever. The *sapræmic* fever is one, therefore, which is evoked by the entrance of a chemical substance into the bloodstream, and, as a necessary consequence, it disappears directly all possible source of absorption of ptomaines is removed.

But in thus entering the threshold of the subject of SEPTIC DISEASE we must first take note of another pathological (febrile) condition, which is possibly sometimes confounded with *sapræmia*. We refer to poisoning by the so-called blood-ferment. It has now for some years been recognised that the direct agent in the production of fever is usually a derivative (a non-organised substance) of animal tissues. Volkmann and Genzmer, following the line of thought already pioneered by Billroth and Weber, came to the conclusion that the cause of the pyrexia, in cases which had been operated on strictly antiseptically, was a hypothetical substance, 'pyrogen,' which was a derivative of the damaged portions of the tissues operated upon. The researches of Bergmann's pupils—notably Angerer, Edelberg, Köhler, and others—have vividly illuminated this obscure point by their experiments with blood-ferment and the various constituents of the blood. We will here preface their conclusions by recalling to mind the conditions under which ferment-poisoning most probably arises. In cases where considerable venous oozing has occurred, the wound-cavity is full of black clot or black treacly serous discharge, this bloody débris being frightfully septic if the antiseptic precautions have failed; but, if these are successful, of course it is perfectly aseptic according to the tests at present at our disposal, so that that complication does not exist. Further, it is a necessary condition that the drainage of the wound should have been insufficient, and consequently a positive pressure set up in the interior of the wound, so as to mechanically aid the

absorption of its fluid contents. Both conditions are not infrequently produced by the removal of large tumours, &c., from the fossæ of the body.

The most noteworthy contents of the wound, then, are—(1) partly clotted blood, (2) serum (simple), (3) serous exudation, (4) blood-pigments (hæmoglobin, &c.), (5) blood-ferment (Schmidt). Besides these well-known substances there are, no doubt, others to which perhaps some of the effects to be noted presently are due; among these substances the body recently separated by Wooldridge is particularly to be noted.

All the foregoing components of such wound-discharge are pyrogenous; injected into the blood-stream of a healthy animal, each of them excites more or less pyrexia. The injection of a solution of blood-ferment produces symptoms exactly similar to those which follow the injection of sepsin, for there soon ensue tremors, vomiting, cramps, and bloody diarrhœa, while the temperature rises to over 105° .

Enough has been said to show that in 'ferment-poisoning,' as at present understood, we have a severe pyrexial condition, due to the action of the ferment on the central nervous system (any ferment will do the same thing—viz. pepsin, trypsin, &c.), and that, recognising the possible occurrence of this condition, it must always be eliminated in framing a diagnosis in a supposed case of sapraemia.

The etiology of sapraemia is at first sight simple enough—viz. the setting up of ordinary decomposition in a wound which is imperfectly drained; but, in reality, there are more complex conditions attendant upon the course of the putrefaction. These external conditions determine the form of sepsin produced, and hence indirectly the symptoms. Thus, quite recently, Schmiedeberg and a pupil have found that the original ptomaine, called sepsin, is only to be obtained under certain definite atmospheric and other conditions. The same fact is well known to mycologists to influence the evolution of Davaine's septiciæmia.

Similarly, the duration of the 'incubation period,' or rather 'latent period,' which elapses before the first symptoms of poisoning appear, varies directly with the dose, so that no general rule can be laid down on this point.

Next, we must consider briefly the mode of entrance and exit of the poison. As a rule, the poison is absorbed from the cavity of a foul wound by the veins and lym-

phatics, and it may easily be observed, clinically, that the absorption is largely influenced by the (mechanical) tension of the decomposed discharges in the wound. When, however, there is a septic inflammatory process about the mouth or pharynx, as in *cancrum oris*, &c., then the patient swallows quantities of putrid stuff; and in that case, of course, the absorption is *per* the lymphatics of the intestine and stomach. Finally, where the nose has been the seat of primary putrid inflammation, sapraemia has followed the inhalation of the poison, and the same thing has been observed in the lower animals.

As described in the articles on SEPSIN and SEPTIC DISEASES, the poison is mainly excreted by the kidneys.

Symptomatology.—Just as in the lower animal the subject of experiment, so in the human being, the most prominent symptoms are those produced by disturbance of the nervous system. The first effect of absorption of a ptomaine or sepsin-like substance is headache (frequently very severe); this is followed by nausea and vomiting. A slight rigor may announce the commencement of the rise of temperature, which usually reaches 101° – 103° F., and very rarely 104° ; the pyrexia is a continued fever until the wound is thoroughly washed out with disinfectant lotion and completely drained, when it disappears at once. (This immediate effect proves that the sapraemic state is due to the absorption of a simple chemical substance, and is in no sense of the word an infective condition.)

Marked changes occur simultaneously in the blood; the patient becomes anæmic, for the red blood-corpuscles vary directly with the amount of poison circulating. There is some leucocytosis also, but the greatest effect is on the number of red discs.

At the same time the excretory organs, which are occupied in getting rid of the poison, are notably affected. The skin is cold and clammy, the urine scanty and concentrated, and sometimes there is diarrhœa, which more rarely is bloody. Diarrhœa, in fact, is next in importance as a leading symptom to those evoked from the nervous system. In final stages, if not previously relieved, the patient becomes delirious, and then the delirium passes into fatal coma. The symptoms will differ according to the difference in the kind of decomposition set up, since the resulting ptomaine poison will be different. See SEPSIN.

Pathological Anatomy.—There is little to be found in the post-mortem appearances

of such a case. The most obvious changes are usually found in the alimentary canal, in the shape of violent gastro-intestinal inflammation, the mucous membrane being intensely congested, small extravasations of blood occurring here and there, and Peyer's patches especially swollen and reddened. Similar small extravasations of blood or petechiæ are found beneath the serous membranes. The central nervous system exhibits marked congestion also of the meninges, and occasional hæmorrhagic petechiæ.

The glandular organs, the liver and kidneys, but especially the latter, show well-marked bloody swelling, while the spleen is frequently (but not invariably) swollen. As has been observed in other septic diseases, the corpse of a person who has died of sapræmia becomes putrid very rapidly.

Treatment.—Fortunately, the treatment of this variety of septic disease is easy and almost always very successful, since it simply consists in the thorough cleansing of all putrid stuff from any of the cavities (especially mucous ones) of the body. All wound-cavities, &c., must be freely drained by fresh incision, large tubes being inserted as a preliminary measure, and are then to be freely syringed out with strong disinfectants—e.g. 1 in 20 carbolic acid, &c. In cases where the sapræmic state follows on the advent of a septic inflammatory process, that must be treated by free incision and washing under anti-septic precautions.

Although the local treatment is the one essential point in successfully combating sapræmia, still, there are other factors in the etiology, &c., of the disease which have to be considered and met. Thus, for instance, there is the secondary anæmia and leucocytosis. This is to be treated with iron and quinine. The former is best given as dialysed iron, $\mathfrak{m}x.$ bis die, and the latter simply dissolved in dilute acid, 15 grains per diem to commence with, and increased as soon as possible. But it will be observed of a series of cases that the symptoms differ to an obvious extent. This is doubtless due to the difference in the kind of ptomaine which may be doing the mischief. *See SEPSIN.* And it may occasionally happen where there are very distinct minor nerve-symptoms—e.g. dilatation of the pupil, dryness of the throat, &c.—that the condition will be best met by administering the vegetable alkaloid which is antagonistic to the one that appears to be imitated by the particular ptomaine under

observation. Thus, if the above-mentioned symptoms were present, it might be of advantage to inject eserine hypodermically. *See HYPODERMIC INJECTION.*

Finally, we would repeat that sapræmia is usually a complication of some infective disease, and that altogether it may be treated apparently successfully in a few days. The chance of the patient's having contracted pyæmia, &c., must be borne in mind. This is notably the case where the sapræmia is of puerperal origin.

Prognosis.—Good, if a simple case.

VICTOR HORSLEY.

SARCOCELE. *See* TESTIS, Diseases of the.

SARCOMA.—*Structure.*—The sarcomata may be defined as tumours of connective-tissue origin, composed of connective-tissue cells. There is often no definite stroma, and, when present, it is—with one rare exception—not arranged in the form of definite alveoli, the cells being uniformly distributed throughout the tumour. The sarcomata are generally largely supplied with blood-vessels, the smallest of which are extremely thin-walled and sometimes appear as channels bounded merely by the cells of the growth. No lymphatics have ever been demonstrated. The cells multiply by fission.

The sarcomata may be conveniently divided into four chief groups—(i.) *round-celled*, (ii.) *spindle-celled*, (iii.) *mixed-celled*, (iv.) *giant-celled* or *myeloid*.

(i.) **ROUND-CELLED SARCOMATA.**—These tumours are composed of round, granular cells of connective-tissue type, frequently multi-nucleated, not generally varying in size in any individual tumour, embedded in a soft, granular, or homogeneous matrix, abundantly supplied with blood-vessels. In some tumours the cells are no larger than leucocytes—small round-celled sarcoma; in others they are more than double or treble this size—large round-celled sarcoma. The cells have no definite cell-wall, and there is often but little protoplasm around the nucleus.

(ii.) **SPINDLE-CELLED SARCOMATA.**—The spindle-celled sarcomata consist of closely packed spindle, oval, fusiform, and oat-shaped cells, generally granular and often multi-nucleated, embedded in a homogeneous matrix. The cells are for the most part arranged with their long axes parallel, but are frequently collected into interlacing bundles. They vary in size in different tumours, but in any individual growth are frequently of

the same diameters throughout. In the small spindle-celled variety their diameter does not exceed that of a leucocyte, and is about one-fourth that of their length, while in the large spindle-celled sarcomas, the cells are sometimes as much as five or six times these dimensions.

(iii.) **MIXED-CELLED SARCOMATA.**—The mixed-celled sarcomas, as their name implies, are composed of cells of various forms, such as may be met with separately in either of the two previous groups. The cells frequently differ in size as much as in shape.

(iv.) **GIANT-CELLED OR MYELOID SARCOMATA.**—These sarcomata are composed for the most part of spindle or oval cells, such as have been already described. Mingled with them, however, are a varying number of large, irregularly shaped cells, often twenty to thirty times larger than their neighbours, granular, flattened, and containing from ten to forty or more nuclei.

Varieties.—Although all sarcomata may be classified in one of the above four groups, yet it is convenient to subdivide them into several varieties, each of which differs in some important essential from the others. The following are the chief varieties.

MELANOTIC SARCOMA.—These tumours are distinguished by the presence of granules of black or brown pigment, in varying amount, scattered through the growth in a very irregular manner, and often absent in one part of a section, while, in another portion, the structure is hidden by masses of colouring matter. Most of the melanotic tumours belong to the round-celled variety of the sarcomata, but in some cases the pigment is found in spindle-celled growths. The pigment occurs both in the cells and in the matrix. Melanotic sarcomas are also not infrequently 'alveolar' with respect to their stroma. See *Alveolar Sarcoma*.

LYMPHO-SARCOMA.—The lympho-sarcomata are composed of very small round cells, lying in a slender, fibrillated matrix; the cells are no larger than leucocytes, and a section of such a growth is almost a *facsimile* of the more cellular part of a lymphatic gland.

GLIOMA.—The gliomas resemble closely the lympho-sarcomas. Their matrix is precisely similar to the neuroglia tissue in the nerve-centres, being a loose meshwork with branching cells. The sarcoma cells are of the small round variety. See *RETINA*.

ALVEOLAR SARCOMA.—The cells in alveolar sarcoma are generally round, but

may be oval or spindle in shape. They are contained in separate alveoli, formed by bundles of connective-tissue. The amount and consistency of this latter is very variable; it is generally much less than is present in the carcinomata, and is sometimes represented by a few fibres and long spindle-cells placed side by side. It is, in some cases, difficult to distinguish the sections of these growths from the alveolar carcinomata. It should therefore be noted (1) that the cells are generally smaller and more granular, and do not possess a translucent body, as do typical epithelial cells. (2) That in any alveolar sarcoma there is often a portion of the tumour composed simply of typical sarcoma-tissue without alveolation. (3) That the cells may be separated from each other by delicate filaments of connective tissue.

HÆMORRHAGIC SARCOMA.—These sarcomas belong to the round or spindle-celled groups. Their peculiarity consists in the extreme tenuity of their blood-vessels and the consequent liability to hæmorrhage, for as fast as they grow peripherally their central parts are broken down by extravasation of blood into a soft mass, which soon becomes indistinguishable from altered blood-clot, of which, indeed, it is almost entirely composed.

PLEXIFORM SARCOMA OR CYLINDROMA.—This rare form of tumour is essentially a sarcoma, some of the cells of which have undergone a hyaline degeneration. The unaltered masses of cells thus appear on section to be contained in alveoli, the walls of which are composed of hyaline material. The cells are generally round, but not infrequently polygonal, are closely packed, and not apparently separated by any intercellular substance. In some cases, the hyaline degeneration may be traced as commencing in the walls of the blood-vessels.

PSAMMOMA—PEARL TUMOUR.—This form of sarcoma has hitherto been found only within the cranial cavity, and, usually, in connection with the pineal gland. It is characterised by the presence of concentric calcareous masses, surrounded by fibrous tissue and attached to fibrous trabeculae.

Degenerative processes in the Sarcomata.—The most common form of degeneration seen in the sarcomata is that known as 'mucoid.' It usually commences in the most central parts of the growth by the distension of the cells with a clear gelatinous fluid, the cells burst, and the mucous fluid is discharged. In some cases the matrix seems to undergo a similar change. The result of

this process is the gradual liquefaction of the tumour and the formation of a cyst. The degeneration frequently commences at several separate foci, so that multiple cysts are formed. Sarcomata may also be the seat of fatty degeneration.

MIXED TUMOURS OF CONNECTIVE-TISSUE TYPE.—The whole of the connective-tissue tumours originate by the proliferation of connective-tissue cells. In any case where the tendency is for these cells simply to *multiply*, a sarcomatous tumour results; and where, in addition, no tendency whatever to *develop* into one of the adult forms of connective tissue is present, the tumour is composed simply of round cells—a round-celled sarcoma. The first evidence of development is seen in the elongation of the cells into spindles or ovals, and the production of a spindle-celled sarcoma. But in many tumours a further tendency to development is present; and, inasmuch as from connective-tissue cells any of the connective tissues may be built, the sarcoma cells become variously mingled with fibrous tissue, cartilage, bone, fat, &c. Supposing that the bulk of the tumour continues cellular, the name sarcoma is still retained, and an adjective, indicating the nature of the developed tissue is prefixed—e.g. fibro-sarcoma, chondro-sarcoma, &c. It is at this point that great difficulty often arises as to whether a growth is, from microscopical examination, to be considered innocent or malignant. For the fibro-sarcomas merge imperceptibly into the sarcomas on the one hand and the fibromas on the other; the chondro-sarcomas into the chondromas; the osteo-sarcomas into the osteomas, and so forth. From a microscopical point of view, it must be laid down that any tumour in which are collected masses of connective-tissue cells must be placed amongst the sarcomata, whilst those in which no such collections are present belong to the innocent class of connective-tissue tumours.

It may be well to describe briefly the general structure of the four most common forms of mixed growth:—

(1) **FIBRO-SARCOMA.**—This form of tumour generally belongs to the spindle-celled group, and was formerly described as 'recurrent fibroid.' The spindle cells are often large, and are mixed both with young connective-tissue and with broad bands of fully developed fibrous tissue.

(2) **MYXO-SARCOMA.**—In myxo-sarcoma the stroma of the tumour consists of branching cells enclosing spaces, in which is contained a clear mucous fluid. In these

spaces are also sarcoma cells. These growths gradually fade into the class of soft fibromas and true myxomas, and from these it is often difficult to separate them.

(3) **OSTEO-SARCOMA.**—This form of tumour occurs only in bone. It consists of a varying amount of sarcomatous cells, mingled with and enclosed by bone trabeculae. *See TUMOURS OF BONE.*

(4) **CHONDRO-SARCOMA.**—The cartilage met with in this form of growth may be either fibrous or hyaline; the sarcoma cells are either round or oval.

The naked-eye appearances of the sarcomata vary indefinitely. In shape, size, and outline no two are alike. On section, the sarcomas that are unmingled with other tissue may be soft, brain-like, and pulpy, readily breaking down on pressure; frequently they possess a gelatinous semi-translucent structure; frequently also they are of a red and fleshy appearance; in any case they may be more or less infiltrated with blood. In one respect they differ, however, from all other tumours—namely, in the homogeneous appearance of their cut section, for, in a typical sarcoma no appearance of fibrillation or of lobulation is to be found. Of course, in proportion as the sarcoma tissue is mingled with fibrous, cartilaginous, or other structures, so the appearance on section will differ. Again, where degenerative changes have been in progress, a variable amount of cystic degeneration, with varying degrees of consistence, will be found.

On section, the sarcomata often appear to be encapsuled, their edges being rounded and apparently well-defined. But although in some few cases they are contained in a pretty definite cyst-wall, in by far the majority of instances the appearance of a capsule is misleading, and, on attempting to separate the new growth from the surrounding tissues, they will be found almost inseparably blended. In other sarcomata, and these the most malignant and rapidly growing, there is no appearance of a capsule, and the tumour infiltrates the surrounding parts in an irregular fashion, being altogether inseparable from the tissues in which it grows.

To the naked eye the *hæmorrhagic sarcomata* often appear simply as hæmatomas, but if careful examination be made, their cyst-wall will almost invariably show evidence of new growth in some part of its circumference. They generally contain both fluid and clotted blood of a dark colour.

The *myeloid tumours* of bone have in part a red-brown or maroon colour (not

unlike that of the normal heart), which when present gives to them a very typical appearance. These growths often possess a pretty definite bony cyst-wall, from which they may easily be shelled out. They are very prone to undergo degenerative changes, so that the hollow formed by the expanded bone is frequently found filled with a broken-down pulp. In some cases, large vessels open into the cyst-like cavities thus formed and produce an evident pulsation, thus forming the so-called 'pulsating tumours of bone.'

The *periosteal sarcomas* of the long bones grow beneath, and strip up the periosteum; they infiltrate both it and the subjacent bone. The most superficial parts of them resemble the sarcomas as already described, but in their deeper portions they are usually completely ossified. They are never encapsuled. See TUMOURS OF BONE.

The *Localities* in which the sarcomata grow are very various. They may develop in almost any part of the body, for connective tissue is to be found in every organ and tissue to a greater or less extent. There are, nevertheless, certain situations in which sarcomata are more common than elsewhere.

The *round-celled* groups are found in the secreting glands—e.g. the testes, parotid, and sometimes the breast. That variety called 'alveolar' occurs chiefly in the skin; the melanotic variety in the skin and in the eyeball; the lympho-sarcomata in the lymphatic glands.

The *spindle-celled* sarcomata occur chiefly in the intermuscular fasciæ and subcutaneous tissues—as periosteal tumours of the long bones, especially of the femur and tibia; also in some of the glands, especially the breast and parotid.

The *mixed-celled* sarcomata are also found chiefly in the connective tissues of the extremities and in the periosteum of the long bones.

The *myeloid* tumours grow inside the long bones, which they tend to expand in their growth; they are found chiefly in the articular ends of the femur, tibia, and humerus. Apart from the long bones, myeloid growths are most commonly met with in the superior and inferior maxillæ.

The *gliomas* are found either in the eyeball or else in the brain and spinal cord.

The *hæmorrhagic sarcomas* occur almost invariably in the connective tissues of the extremities.

Of the various mixed tumours of connective-tissue type the *fibro-sarcomas* are the most common. They occur in the sub-

cutaneous tissues, in the periosteum of the long bones, and in the breast; they are the most usual form of sarcoma met with in the latter organ.

The *chondro-sarcomas* grow more particularly in the articular ends of the long bones, in the parotid, the testis, and very rarely in the breast.

The *osteosarcomas* grow in the bones, especially those of the extremities.

The *myxo-sarcomas* are found in the mucous cavities, such as the nose and antrum. They occur also in the uterus and in the parotid glands.

Clinical Characters of the Sarcomata. In speaking of the sarcomata in general, it is impossible to describe with anything like accuracy the special characters which appertain to the various tumours of this class, for they vary immensely according to their locality.

These growths may be said to occur more frequently in the young and middle-aged than in the old, to follow injuries with tolerable frequency, and to grow rapidly. The more malignant the tumour the more rapidly it grows. The amount of pain caused by such a growth necessarily varies greatly; frequently no pain or tenderness is complained of.

When in a situation favourable for examination, a sarcoma presents itself as an irregularly rounded or oval swelling, sometimes a little lobulated, but with a surface generally smooth, adherent to the parts amongst which it lies, and therefore more or less fixed, and firm, elastic, or semifluctuating to the touch. The more rapid the growth of the tumour, the more soft and fluctuating is it as a rule. It is usually very vascular, and attention is called to this by the enlarged and tortuous veins in its neighbourhood.

Of the varieties of the sarcomata the following points may be briefly noted:—

The *melanotic sarcomata* of the skin generally develop in the site of a previously existing mole or wart, sometimes when either of them has been irritated by caustics or by imperfect attempts at removal. Rapid growth in a mole or wart, previously quiescent, should then always be looked upon with great suspicion, and radical treatment never delayed. In the later stages of melanotic sarcoma multiple growths are common, and pigment-granules may be found in the urine.

The *hæmorrhagic sarcomata* are rapidly forming tumours, evidently fluctuating, situated generally on one or other extremity, with no signs of inflammation, and,

when tapped, yielding usually dark-coloured blood. They rapidly refill after tapping, and continue to increase in size—a point to be noticed, for simple hæmatomas do not increase unless they become the seat of suppurative changes.

The *sarcomas of bone* grow almost invariably at the articular ends of the long bones and in the bones of the face. The myeloid growths, commencing within the cancellous tissue, expand the bone in their growth, and so become covered by merely a thin shell which, on pressure, is readily indented, with a crackling sensation. This bony crackling is never present in the subperiosteal sarcomas. Occasionally, also, the central tumours of bone are the seat of distinct pulsation, caused by the opening of large vessels into the cysts formed by degeneration of the tumour-mass.

The *periosteal sarcomas* are more rapid in their growth than the endosteal; they grow on one aspect of the bone, and do not pulsate. Neither the central nor the periosteal growths often cause glandular affection. See TUMOURS OF BONE.

Signs of Degeneration in Sarcomata.—As already described, the sarcomata may undergo degenerative changes, resulting in the formation of cysts containing fluid within the tumour-mass. These collections of fluid necessarily yield a distinct sense of fluctuation, and those parts also which are yet in the process of degeneration, but which, though succulent, are not yet fluid, feel in a corresponding degree softer than the rest of the sarcomatous growth. Thus, in a sarcoma that is degenerating, the whole mass varies in consistency at different points.

Signs of Inflammation in the Sarcomata.—Although, as a rule, the sarcomata grow without any definite signs of inflammation, it must nevertheless be remembered that, very rarely, not only may such tumours show all the local signs of inflammation, but that pus may be formed within the new growth itself, and the abscess may come to the surface and burst, in a manner which differs in no way from that which pertains to simple abscess situated amidst the tissues of the body. So, pain, redness, heat, and swelling are all compatible with the presence of a sarcoma, and, yet further, the temperature may be raised and may continue at 101° or 102° F. for many days, even when there is no suppuration.

Differential Diagnosis of the Sarcomata.—It is not possible in the present article to deal at all fully with the differential diagnosis of the sarcomata; all

that is therefore attempted is to point out the chief only of those swellings which may be mistaken for the sarcomas.

To facilitate this, the writers suggest that the tumours in question should be considered according as they are found—A. In the soft connective tissues. B. In the glands. C. In the bones.

A. *In the soft connective tissues* the sarcomata must be especially distinguished from—1. Cysts. 2. Abscesses. 3. Hæmatomas. 4. Syphilitic swellings. 5. Innocent tumours.

1. *Simple or serous Cysts.*—The locality of the swelling may be such as to make it highly improbable that it is cystic. The growth may have been more rapid than is usual in cysts. If large and superficial, cysts are often translucent—sarcomas never. If tapped with an aspirator or fine trocar, a simple cyst will be entirely emptied and its contained fluid will be found clear and serous. If a solid sarcoma be tapped, only bright blood will escape; if one that is undergoing cystic degeneration, the fluid that is drawn off will be dark and blood-stained, and, when it has ceased to flow, some of the swelling will still remain and can be felt to be solid. Fluctuation is much more marked in a cyst, and is readily transmitted from its extreme boundaries. This is not usual in sarcomas, even in those that are undergoing cystic degeneration.

2. *Abscesses* which are chronic and deeply seated may simulate sarcomas very closely, but some of the signs of inflammation will generally be present, and often there is, if nothing else, a little cedema of the superjacent skin. On the other hand, a sarcoma that is inflamed may closely simulate an abscess. In many cases, tapping alone will clear up the diagnosis.

3. *Hæmatomas*, as already mentioned, may closely simulate or be simulated by the hæmorrhagic sarcomas. The rapidity of growth, the rapid refilling after tapping, and the increase in size, independently of any inflammatory changes, will usually serve to distinguish this variety of sarcoma. For it must be remembered that tapping alone will not decide the question, the dark-coloured bloody fluid answering equally well for the contents of either a hæmorrhagic sarcoma or a hæmatoma, and the size being as much reduced in the one as in the other. The latter swellings, however, do not rapidly increase in size unless they become the seat of suppuration.

4. The diagnosis from *Syphilitic Gummata* is sometimes very difficult, and often at first impossible; for although other evi-

dence of syphilis in the same individual will make the diagnosis of gumma probable, it will not necessarily disprove the sarcomatous nature of the growth. As a rule, a decision will be most readily arrived at by placing the patient under antisyphilitic treatment.

5. *From Innocent Tumours.*—The lipomata and soft fibromata are the innocent tumours which, to the touch, most resemble sarcoma, but it is chiefly when growing in unusual situations or existing under unusual conditions, such as being injured, inflamed, &c., that any difficulty of diagnosis arises. A satisfactory conclusion will generally be arrived at by a careful comparison of the physical characters of the sarcomata with those of the innocent tumours. But the rapidity of the growth is the most essential particular into which inquiry should be made, the increase in size of the malignant tumours being very much more rapid than that of the innocent one.

Nævoid growths also may simulate sarcomata. Their congenital occurrence and great vascularity, combined with the fact that their size may be diminished on pressure, will generally, but not always, serve to distinguish them. In cases of large subcutaneous nævi the diagnosis may be very difficult.

B. *In the Secreting Glands.*—In the breast, parotid, and testis more particularly, the sarcomata have to be diagnosed from—1. Carcinomata. 2. Tumours of an innocent nature. 3. Cysts and abscesses.

1. From the *Carcinomata* the sarcomas may be distinguished, in most cases, by attention to the descriptions already given of the clinical characters of these growths. See CARCINOMA. Diagnosis is not of material importance, for the treatment of each class of tumours is alike. Carcinomas are rare in the parotid, sarcomas common.

2. From *Innocent Tumours* the diagnosis may be made by attention to the rapidity of growth, the infiltration of the tissues, and the affection of the general health, as well as by the physical characters of the growth itself.

Such special swellings as hæmatocele and chronic orchitis are considered elsewhere. A tumour of long duration must not be judged innocent from that fact alone. For, though of slow growth and apparently innocent, it may after some years begin to grow rapidly and exhibit all the signs of malignancy.

3. From *Abscesses and Cysts* the diagnosis may be made in a similar manner to that already described in dealing with sar-

comas of the soft connective-tissues, bearing in mind, in the case of abscesses, any points of special history which may belong to the part of the body affected—e.g. history of recent parturition and lactation in the case of the mammary gland, of urethral inflammation in the case of the testis, &c.

C. *In the Bones.*—In the bones the sarcomas are chiefly simulated by or else simulate—1. Joint-disease. 2. Quiet necrosis without suppuration. 3. Chronic periostitis.

1. From *Joint-disease* the sarcomata may be diagnosed by the healthy condition of the patient, by the rapid increase in size of the swelling, the enlarged and tortuous veins on the surface, by bulging more on one side of the articulation than another, by the frequently painless, though limited, movement of the joint itself, by the evident implication of one bone greatly in excess of the other, by the absence of inflammation and of starting pain at night, and by the failure of all treatment. It must be clearly remembered that the joint may itself become diseased by the encroachment of the tumour. In these cases of sarcoma signs of inflammation are often well-marked, and great care is frequently necessary to establish a diagnosis.

When the tumour grows from the centre of the bone, and more particularly when of the myeloid variety, the presence of 'egg-shell' crackling, and occasionally of pulsation, will show clearly the nature of the swelling.

2 and 3. *Swellings on bones the result of quiet necrosis* or else of *simple or syphilitic chronic periostitis* may be considered together. In many cases no difficulty arises in separating such inflammatory swellings from the sarcomata of bone, but, in those instances in which the inflammatory symptoms are but little marked, the diagnosis may be so difficult that, without incising the swelling, it is not possible to be certain of its nature. It is well to bear in mind, in considering such a case, that the sarcomata almost invariably grow at the epiphysal ends of the bones, so that any tumour situated on the shaft is not likely to be sarcomatous. Moreover, in cases where the swelling is due to periostitis, its shape is suggestive rather of enlargement of the bone, with preservation of the general outline, than of a tumour presenting on one aspect alone; whilst, to the touch, the sarcomatous growth is not hard and incompressible in its whole extent, but in parts is often soft and elastic. Reliance must not be too strongly placed on an increase or

abnormally wide variation of the body temperature, for in the sarcomata of bone such increase and variation may be present, and the temperature chart may be indistinguishable from that of hectic fever. Again, if the swelling be due to chronic periostitis, treatment by counter-irritants and absorbents, especially iodide of potassium will often result in its disappearance; though, if quiet necrosis be at the bottom of the inflammation, this disappearance will not take place. In all doubtful cases an exploratory incision should not be too long delayed. And even after such incision has been made the diagnosis is not always easy, for the thickened and inflamed soft tissues around the dead bone may closely resemble sarcoma.

For *Etiology; Clinical differences between Malignant and innocent tumours; and for Treatment of the sarcomata*, see MALIGNANT TUMOURS.

W. MORRANT BAKER.
ANTHONY A. BOWLBY.

SAYRE'S SPLINT for the hip consists of a metal bar, which reaches, as an outside thigh-splint, from the pelvis to the knee. This bar is composed of two pieces, one of which slides within the other and is capable of being fixed, as required, by a ratchet. The upper end of this bar is connected, by means of a ball-and-socket joint, to a padded metal band, which is meant to encircle the pelvis; from the lower end of the bar two arches pass off with sufficient span to reach over the front of the thigh to the inner side of it, where they become continuous with a short longitudinal bar. At the lower end of both the outer and inner longitudinal bars there is a pulley, and just above the latter there is a buckle. There is also a perineal band which, when the splint is applied, is buckled in front and behind to the pelvic girdle. To apply the splint, two pieces of strapping, with a piece of webbing stitched to one end of each, should be fixed to the inner and outer surfaces of the thigh by another piece wound spirally round the limb, and by a few turns of bandage placed over all. The pelvic girdle and perineal band should next be adjusted, the metal bar being placed in position along the outer side of the limb; and then the pieces of webbing, above mentioned, should be carried round the pulleys at the lower end of the splint, and fastened up tightly to the buckles. By turning a key the splint can be lengthened, and as the thigh is fixed by the strapping to the lower end of the splint, and as the perineal band

will check upward displacement of the pelvic girdle, the lengthening of the splint will cause extension at the hip-joint. See HIP-DISEASE. BILTON POLLARD.

SCABIES, or the ITCH.—*Definition.*—A contagious disease of the skin, due to the presence of a small mite known as the *Acarus scabiei*. See *Acarus Scabiei*, under ACARUS.

Course and Symptoms.—The female acarus penetrates and burrows into the substance of the epidermis, and oftentimes into the hair-follicles. In this burrow or cuniculus, which in the early stages is not well-marked, and in cleanly people is difficult of detection, the female, being unable to retreat by reason of certain projections or spines with which its body is armed, lives, lays eggs, and dies; the male, on the other hand, lives on the surface of the skin, some say in the shallower burrows. The lesions produced depend upon the depth of penetration of the acarus and the susceptibility of the individual attacked. The earliest signs are the formation of minute inflammatory macules, papules, and vesicles. The sympathetic irritation is very considerable, extending to parts far removed from the seat of the acarus or acari. If neglected, the disease spreads daily, until at the end of three or four weeks all the characteristic parts have become affected. The position of the burrow is beneath the horny layer of the epidermis and in the upper part of the rete. The burrow is slightly raised and very tortuous, and its average length is one-fifth of an inch, but occasionally it reaches the length of two or even three inches. In appearance it is of a whitish or yellow colour, and, seen through a glass, is either dotted from ova and excreta or black from dirt. A vesicle is often formed at the point of entrance to the burrow, at the other end of which will be found the acarus. As a rule, burrows are only to be discovered between the fingers and toes, on the wrists, and on the navel and penis; and even on these parts they may be completely destroyed by scratching, or obscured by much pustular eruption and scabs. To remove an acarus, it is necessary to place a needle flat upon the surface of the skin—and not perpendicularly—the point is then inserted into the burrow at right angles to its course, and on slowly moving it away from the vesicular end, the acarus, if alive, will adhere to the needle.

The eruption, which is of an eczematous character, is always accompanied by much

itching at night, produced by the warmth of the bedclothes. Papules, vesicles, and pustules may all be present at the same time. The papules are usually numerous, always small, and, according to Dr. Liveing, generally more isolated and scattered than those of simple eczema, and do not early develop into large excoriated patches. The vesicles are of various shapes and sizes, usually have inflamed bases, and often show parts of burrows on their summits, in which condition they may remain or, passing into pustules, increase to a considerable size and extend. The disease usually begins on the hands, especially between the fingers, whence it is commonly communicated to the penis in urination. In women, it attacks the mammae about the region of the nipple, and in all cases shows a preference for the softer regions of the trunk, especially the warmer parts, and also the inner surfaces of the limbs. In adults, the disease is never found either on the scalp or face—those parts being much exposed to cold—and only occasionally in infants. In young children, the buttocks and feet are often affected. It displays a preference for those parts of the skin which are subject to any pressure, as, for instance, beneath the stays, garters, or belt, and upon the buttocks of people who sit much. Scratching produces important secondary lesions—excoriations, torn papules, vesicles, and pustules—which result in crusts of blood, serum, and pus, and also general dermatitis, with infiltration, thickening, and pigmentation. Irritation is not always confined to the immediate neighbourhood of the acari, and the sympathetic itching caused by them, in distant parts, accounts for the widespread eruption apparently so out of proportion to the cause. Cases of so-called Norwegian scabies—which is a more serious, exaggerated, and chronic form, or an advanced stage of the same disease, resulting from neglect—have been known to last a lifetime. The whole integument becomes chronically inflamed and covered with pustules and extensive crusts, in which numerous acari and ova are found.

Diagnosis.—The only diseases with which scabies can be confounded are eczema and prurigo, and the following are the exact points which distinguish it from them:—The position of the eruption; the time and amount of irritation; the presence of burrows and acari; and the history of contagion. In scabies, the eruption is limited to certain parts—between the fingers or toes, fronts of wrists; while in eczema the erup-

tion spreads from the margin of the patches, and is never limited to these parts. In prurigo the hands are only slightly affected—usually only when there is secondary eczema—the characteristic parts attacked being the front and back of the trunk and the extensor surfaces of the limbs. The irritation in scabies is always worse when the skin is warm, but as this is also the case to a modified extent in both eczema and prurigo, the other points are the only certain signs whereby scabies may be distinguished from the two diseases mentioned.

Treatment.—This consists in the complete destruction of the acari and their ova. But, in order to do this effectively, it is necessary to open up the burrows in which they are concealed. This part of the treatment is at times rendered somewhat difficult by reason of the secondary eczema. The body should be soaked in a hot bath, after which all parts, where burrows are known to exist, should be freely rubbed with soft soap and a brush, and the entire surface then covered with an ointment containing some parasiticide. In this way the scabs will be removed, the burrows will be torn open, and the acari and their ova destroyed. After the process has been repeated once or twice, according to circumstances, the disease itself will be cured, although some eczema may remain as the result either of the disease or of the treatment. The effect of all parasiticides is more or less irritating, and as some people suffer much from them, care must be taken in their selection.

The two essentials in the treatment—that is to say, the opening up of the burrows and the destruction of the acari and ova—can be combined in one remedy, the lotion known as Vlemingx's solution, \mathcal{R} Calcis \mathfrak{z} ss., Sulph. precip. \mathfrak{z} j., Aq. destill. \mathfrak{t} zv. This, rubbed in forcibly for half an hour and followed by a hot bath with plenty of soap, will often effect an immediate cure. But it is a rough method, and should only be used when time is a great object. A milder plan, and one almost as rapid in its results, is to combine the soft soap with the parasiticide, as in Hebra's modification of Wilkinson's ointment—Sulph. præcip. et picis liq. $\mathfrak{a}\mathfrak{a}$ \mathfrak{z} vj.; Saponis viridis et adipis $\mathfrak{a}\mathfrak{a}$ lb. j.; Cretæ \mathfrak{z} iv. Fiat unguentum.

The sulphur vapour bath is recommended by some authorities, but it is far less effectual than ointments. If the sulphur ointment of the B.P. be employed, it should be reduced to, at any rate, one-third its strength. It is necessary to remark

that the antiparasitic remedies should be discontinued as soon as possible, and that the subsequent eczema should be treated with soothing powders, lotions, or ointments. It is also important to note that the underclothes worn by the patient should be baked in an oven, so that all ova may be destroyed.

The following applications are all most useful for the destruction of the acari:—

R. Olei cadini et sulph. præcip. āā ʒiij.; Glycerini amyli fʒvj.; Adipis benzoati ad ʒiij.

R. Styracis liquidi fʒj.; Adipis ʒij.

R. Styracis liquidi fʒj.; Sp. vini rect. fʒij.; Ol. olivæ fʒj. Fiat linimentum.

R. Pulv. staphisagriæ ʒj.; Adipis ʒiij.

R. Balsami Peruviani ʒss. vel ʒj.; Adipis ʒj. Suitable when for some special reason sulphur is not advisable.

R. Naphthol. fʒss.; Adipis ʒj.

It is quite unnecessary to employ any internal treatment in Scabies.

MALCOLM MORRIS.

SCALDS. See BURNS.

SCALDS OF THE GLOTTIS are most commonly met with in infants or young children, from attempting to drink out of the spout of a kettle; or else in adults from the inhalation of steam in boiler accidents, or of ignited gas in explosions. In the latter, the lips and face, and even the whole body, are involved; in the former, the scalding steam is drawn into the interior of the larynx, and even into the trachea, by the sudden inspiration which precedes the cry of pain caused by the contact of the boiling water.

The severity of the injury presents considerable variations in each case. The mouth itself may escape so completely that, on casual inspection, there is nothing serious visible, while in reality the edges of the epiglottis are scorched and shrivelled, and the upper and back part of the larynx swollen and blistered; or the lips and tongue may be reddened and covered with vesicles full of exuded lymph, or with shreds of yellowish epithelium hanging down from the swollen papillæ. Sometimes, there is merely a slight degree of hyperæmia; at others, particularly if the fluid has entered the mouth, the epithelium is raised up and detached just as in scalds of the skin.

The symptoms are immediate, due to the injury itself, or remote, consequent on the inflammation that always ensues. Severe burning pain is always present: in

a child the screaming is incessant until, partly from exhaustion, partly from the oedema which very rapidly sets in wherever there is any loose connective tissue, the voice fails completely, and there is nothing to be heard but a hoarse, croupy inspiration. Often, the child tries to thrust its hand into its mouth or clutches wildly at its throat. Great restlessness and anxiety, or a continual sense of impending suffocation, are always present. Difficulty of swallowing sets in from the first; dyspnoea may also be immediate, but more often it becomes more marked in the course of a few hours, in consequence of the oedema and inflammation.

Exudation and swelling follow rapidly—most marked, of course, in the submucous tissue of the injured part, and particularly where the fibres are loose and yielding. By the root of the tongue, round the base of the epiglottis, and along the course of the folds leading from its sides to the arytenoid cartilages, are the favourite places. The ventricles are rarely much involved, and the true vocal cords, where there is no submucous tissue, hardly ever. The epiglottis itself may appear hard and shrivelled; the folds behind it are swollen up so that they can easily be felt with the finger, or seen, when the tongue is depressed, as smooth, round, semi-translucent masses on either side, reaching nearly across the middle line. Below, in the lower part of the larynx and trachea, similar changes, though of less severity, are not uncommon; probably due to the direct effect of the injury, although perhaps in some instances the result of extension of the inflammation. In short, the appearances are those of acute laryngitis, with more or less oedema of the glottis.

As this stage is reached, generally some few hours after the accident, and often preceded by a period of delusive repose, the symptoms become more and more grave. The dyspnoea, especially, increases slowly and surely, becoming worse the whole time, but interrupted now and then by paroxysmal attacks of asphyxia, each of which seems as if it would prove instantly fatal. Inspiration is much more impeded than expiration, especially in children; the breathing has a hoarse, croupy sound; the voice is completely lost; and with its chest thrown forwards and its chin upwards, so as to secure the greatest muscular aid, the child sits propped up, perfectly quiet, with its whole energy directed to its respiration. The face is pale and cyanosed, the lips dusky, the skin bedewed with perspiration, the pupils dilated, and all the symptoms of

asphyxia are present. At length the child sinks into a state of collapse, or death takes place suddenly during one of the paroxysms.

Later on, if this stage does not prove fatal, inflammatory affections of the bronchi and lungs ensue. The temperature rises, all the signs of fever set in, and a low insidious form of broncho-pneumonia makes its appearance—peculiarly dangerous not only in itself, but also from the circumstances which have preceded it, and the conditions under which it appears.

The *prognosis* is at all times exceedingly grave. The case may sometimes terminate fatally at once, from the shock of the injury. More often the symptoms subside for a short time, and then, especially at night, break out again with a succession of paroxysms, any one of which may be the last; and when this stage has passed, owing to the inflammation that follows, convalescence is always protracted and tedious.

Treatment.—The first object is to confine the inflammation following the injury within the narrowest possible limits, so that there may be free entry for the air, and that the lungs may not collapse or become involved by gradual extension of the mischief. Then, every care must be taken to prevent the access of anything that could irritate the larynx. The mucous membrane becomes intensely sensitive when it is inflamed, and what would hardly be noticed under ordinary conditions, or at most would give rise to a transient cough, may now excite such a paroxysm of spasmodic contraction that death ensues before any relief can be afforded. Finally, there is the question of tracheotomy, or, in children, of laryngo-tracheotomy, either as a preventive measure or to relieve already existing obstruction.

The temperature of the air breathed must be perfectly equable, and it ought to be saturated with moisture. This is best managed by surrounding the cot with curtains, and conducting the steam of a kettle into one corner; in this way cold draughts and dusty air may be completely excluded, but care must be taken not to raise the temperature too high, so as to avoid the intense depression caused by a warm moist atmosphere. Perfect rest is essential; but, as a rule, if the difficulty of breathing is at all great, the patient will remain perfectly quiet of himself. Ice round the neck, applied by means of a collar, and the continual sucking of small fragments, retaining them as long as possible in contact with the fauces, will help to keep the hyperæmia in check and to diminish the sensitiveness.

Bromide of potassium has been recommended for this purpose, but as a rule the symptoms come on before the drug has time to act. Leeches applied to the sternum or at the lower part of the neck, purgatives, and emetics—especially those which act like alum, without leaving behind any lasting depression—are of the greatest service in mild cases. Aconite and antimony are of use occasionally when there is a considerable rise of temperature, and small doses of calomel, gr. j. to gr. ij. every hour, until there are free bilious evacuations, enjoy a high reputation.

If, in spite of treatment, the dyspnoea continues to increase, and if, without there being any marked spasmodic attack, inspiration is becoming more difficult and the chest-walls are falling in, the choice will lie between free scarification of the swollen parts of the larynx, so as to procure the evacuation of as much exudation as possible, or opening the windpipe lower down. The former operation, particularly when the most swollen parts are the ary-epiglottic folds, which is usually the case, may be accomplished without much difficulty, either by means of an instrument devised for the purpose or with an ordinary sharp-pointed bistoury, of which all but the half-inch nearest the point has been guarded by a spirally wound piece of strapping. The folds can easily be felt with the forefinger of the left hand, and free incisions may be made on their upper surface. With reasonable care there is no danger of wounding any important structure, and it is surprising both how little of the exudation comes from a comparatively large wound, and how small that wound becomes when the part resumes its normal dimensions. The chief difficulty arises from the degree of dyspnoea from which the patient is already suffering, and from the spasmodic contraction sometimes induced when the finger touches the larynx.

It is best to postpone tracheotomy as long as possible, but it must not be forgotten that spasmodic contraction may come on with the slightest cause, even on movement, when a larynx is inflamed, and that any of these attacks may prove fatal. The operation gives, it is true, protection from one of the great dangers of this accident, and helps also to prevent collapse of the lung and subsequent hepatisation; but in a child it is a matter of some gravity, and it adds an additional cause for the inflammation of the bronchi and lungs which so commonly follows. But if tracheotomy is reserved to the last, and performed only in cases that are almost desperate, the ill

result must not be laid entirely to the credit of the operation. In all probability, if it were done at an earlier period and in a larger number of cases, instead of being reserved for those in which inflammation has already set in, and probably extended into the bronchi, the results would be very different. In any case it is advisable to insert a soft india-rubber tube as early as possible, so as to avoid the ulceration of the mucous membrane and necrosis of the cartilages, not uncommonly seen after the introduction of metal ones.

C. MANSELL MOULLIN.

SCALP, Injuries and Diseases of the. The skin covering the cranial vault is intimately connected, by means of strong fibrofatty tissue, with the tendon of the occipitofrontalis. These three structures constitute the scalp, whose inner surface, formed by the smooth aponeurosis of the muscle, is attached to the pericranium by loose areolar tissue and small vessels, and is freely movable over it.

HÆMATOMA, or a fluid blood-tumour of the scalp, is often the result of a blow. These tumours are situated either beneath the skin, beneath the aponeurosis, or beneath the pericranium. If blood collects between the skin and the aponeurosis, its amount must be very limited, as the tissue here is unyielding; but if it is poured out beneath the aponeurosis, the extravasation may be very extensive—sufficient indeed to lift the scalp away from the pericranium. It is limited in front and behind by the attachments of the occipito-frontalis, whilst laterally it descends as low as the zygoma, for the lateral edge of the tendon is continued to that bony process by a thin membrane which lies superficial to, but not in immediate relation with, the temporal fascia. Fortunately, the vessels in the subaponeurotic space are small, or this accident would be far from rare. A blood-collection which involves the separation of the pericranium from the skull is known as a **CEPHALHÆMATOMA**, and is necessarily limited to one bone by the dipping in of the pericranium at the sutures. It occurs commonly over the right parietal bone during parturition, or may follow a blow in an infant.

The *treatment* of blood-extravasation of the scalp should be conducted on those general principles which guide the surgeon in the management of hæmatomata occurring in other parts of the body. It should be mainly expectant, for, unless these collections are very extensive, the hope may be indulged in that they will clear up under

the influence of evaporating lotions, and an arrest of the movement of the scalp by means of strapping carefully applied. If these measures fail, antiseptic aspiration may be tried; but if any septic or inflammatory change occur within the tumour, free incision at dependent points must at once be practised, and the whole cavity washed out with some efficient antiseptic agent. Free drainage must then be provided for, and the dressing should be either gauze or wood-wool, impregnated with carbolic acid, iodoform, or corrosive sublimate. Shaving of the head is necessary, if the blood-extravasation be extensive and complete antiseptics be attempted.

WOUNDS OF THE SCALP partake of the same characters which distinguish wounds of other superficial regions. The incised, lacerated, and contused varieties are the most common. They are peculiar in the facts that they do not gape, and that, even if small, they may give rise to a good deal of bleeding, because the arteries lie in the subcutaneous fibrous tissue and are unable to either contract or retract—partly in consequence of the rigidity of this tissue, and partly as a result of the attachment of their outer coats to it. The partial division of vessels is another potent cause of profuse hemorrhage from the scalp. This hemorrhage can always be easily controlled by pressure. The bandages should be carefully applied without undue force, as more than one case has been reported in which a scalp bandage has produced sloughing of the cranial coverings. The hairs of the scalp are so strongly attached that cases are on record in which the scalp had been torn off by force conveyed through the hairs—the latter collectively possessing very considerable strength. Large portions, or even the whole, of the scalp may be stripped off from the vault of the skull without losing vitality, since the scalp carries its blood-supply with it, its arteries lying between the various layers of tissue of which it is composed. The danger of scalp wounds is coincident with and is chiefly caused by the opening up of the subaponeurotic space, the spread of inflammation being so easy in the loose areolar structure which intervenes between the tendon and the pericranium. If the bone is exposed by the stripping up of the pericranium it does not necessarily follow that it will necrose, as it is in most part nourished by the endosteal vessels. It is, however, undoubtedly a fact that the most common cause of intracranial inflammation is injury to the scalp, with stripping up of the pericranium.

Another noteworthy point about injury to the scalp, with exposure or bruising of bone, is that, should unhealthy inflammation ensue, the emissary veins may be the carriers of septic products into those of the diploë, or into the sinuses within the cranium. In either case a fatal pyæmia, preceded by thrombosis and osteitis, is likely to supervene.

Treatment.—Absolute cleanliness and antiseptics are of the first importance in the management of all scalp-wounds. If a large portion of scalp has been stripped off the cranium, infinite pains should be taken to make the whole aseptic by removing the hair and by diligent washing. The torn edges can then be united by sutures, counter-openings being made at dependent points, through which drainage-tubes should be inserted, and over all a carbolic gauze and salicylic wool dressing be accurately adjusted. Thus treated, cases oftentimes apparently the most severe convalesce, especially if the patient be young, with great rapidity. Wounds which do not pass through the occipito-frontalis tendon heal rapidly without any special treatment. Scabs are, however, apt to form over these trivial wounds, and it is necessary therefore to be careful that no wound-secretion remains pent up. Injuries of the scalp are especially dangerous in those cases in which other injuries would be serious, as in patients suffering from alcoholism or albuminuria, or the subjects of hæmophilia. In patients who are sodden with alcohol, delirium tremens, or a low form of inflammation accompanied by a low, muttering delirium, may ensue, which it will tax to the utmost the powers of the surgeon to subdue. In albuminuria, an asthenic form of inflammation is apt to come on which heralds a fatal issue. In hæmophilia, the wounds are best left entirely alone, exposed to the air without any interference. The only treatment which the writer has seen successfully adopted in such cases is the local application and internal administration of turpentine.

After all bad scalp-injuries the patient should be kept at rest for some days, the primæ viæ should be put in order, and the diet should be unstimulating, moderate in quantity, and largely composed of milk and foods made with milk.

INFLAMMATION readily occurs about a wound of the scalp if any secretion be pent up, or if asepsis be not attained. Shaving, free drainage, and poulticing will prevent its extension in most cases. It has, however, a tendency to assume an erysipelatous form, and then the whole scalp may become

'boggy,' and the course of the case will not be so simple. Much redness and swelling are not possible, on account of the anatomical peculiarities of the tissue. Inflammation is most serious when the sub-aponeurotic space is opened, or when the bone is laid bare by the stripping up of the pericranium.

Erysipelas of the Scalp usually follows a wound and may be caused either by the conveyance of infection from another patient, through the air, or by means of tainted sponges, instruments, &c., or may arise *de novo* under conditions which were apparently the least likely to produce it. The early diagnosis between local inflammation, with formation of pus underneath the scalp, and an attack of erysipelas, is in some instances difficult. In the former case the inflammatory focus would be more or less limited and defined, and must have been preceded by local injury. The pus would, moreover (if formed), bag at the dependent and attached borders of the scalp. In the latter case the general constitutional symptoms would probably be more marked, and, at the very commencement of the attack, vomiting and enlargement of the cervical glands would be important points to note. *Cutaneous erysipelas* of the scalp commonly extends to the face, and can usually be with ease subdued by frequently changed warm compresses of lead lotion and by nutritious diet. The temperature may range up to 102° or 103° Fahr., and for two or three nights the patient may suffer from a little delirium. In those cases in which the whole thickness of the scalp is involved and the bone is bare, we have to deal with a *cellulitis* which is extremely dangerous; but, even in the worst cases, free incisions, antiseptic washings, ample diet, perchloride of iron and quinine, with stimulants, will do a great deal to bring about recovery.

Abscess of the scalp is small and unimportant if situated above the aponeurosis, and commonly happens from the scabbing over of a wound before the deeper parts are healed. If pus forms beneath the aponeurosis, the collection may be very extensive and serious. The treatment consists in shaving, free incision at dependent points—above the zygoma, at the upper margin of the orbits or in the occipital region—with antiseptic irrigation and dressings. The *sinuses* which remain after a large abscess of the scalp has been evacuated are sometimes difficult to close. The best way is to adopt Mr. Hilton's plan of securing rest to the scalp by well-applied strapping. *Abscess in the temporal fossa* may be

mentioned in this place. The pus tends to pass down beneath the zygoma, and does not point above it in consequence of the extreme density and strength of the temporal fascia. It should be opened above the zygoma as soon as deep fluctuation can be felt.

Boils and carbuncles occur upon the scalp. A carbuncle in this region may be most serious. It may commence in the soft parts covering the skull or extend to them after first attacking neighbouring parts, such as the back of the neck. See BOILS; CARBUNCLE.

SIMPLE AND MALIGNANT TUMOURS are by no means uncommon on the scalp.

Sebaceous cyst is the most usual form of simple tumour. If congenital, it is known by the name of *dermoid cyst*, occurs frequently near the outer angle of the orbit, and often involves the wall of the cranium. When placed in the median line, the diagnosis from meningocele is almost impossible. See MENINGOCELE. Sebaceous cysts, which are not of congenital origin, occur at any age after puberty, but most frequently in middle life. They may be multiple, and by their gradual increase in size during many years may, in rare cases, involve the cranial vault. The orifice of the obstructed follicle is generally visible, and the tumour itself is round or oval, tense, freely movable, hard, or fluctuating. These cysts can be removed by dissection, or by transfixion and subsequent avulsion of the wall of the sac. No part of the latter must be left, or troublesome after-consequences will ensue. These operations should never be lightly undertaken, and never except in persons in perfect health. The removal of a congenital cyst is more difficult, partly on account of its greater depth from the surface, and in part on account of the thinness and delicacy of the cyst-wall, and the adhesion of the latter to the bone. When a sebaceous cyst ulcerates, the diagnosis from epithelioma is not easy. The base of the ulcerated cyst is movable and not very hard; the granulations exuberant, and there is no evidence of surface-decay; the discharge is offensive, and the glands in the neck might be enlarged. See SEBACEOUS CYSTS.

Epithelioma generally commences as a crack or pimple, and there would be no history of a previous cyst. The base would be hard and fixed, and if at certain points vegetative outgrowths were apparent, the general tendency would exhibit an eroding and destructive character. *Rodent ulcer* not infrequently attacks the scalp primarily,

but it may do so secondarily after destroying a portion of the face. See under CARCINOMA; ULCERS.

The *treatment* of epithelioma and rodent cancer is wide excision. An ulcerated sebaceous cyst must also be excised. In epithelioma the glands in the neck may be implicated so much, by the time the patient is seen, as to make operation unjustifiable. In rodent cancer, the disease must be removed, even if it extends into the bone; and at the close of such an operation, the application of chloride of zinc paste is most useful.

Syphilitic ulceration of the scalp is occasionally most intractable.

The *pachydermatous tumour* of the scalp is very rare. It is a localised fibrous change affecting the skin and deeper tissues. It is movable, and causes much deformity. It has been successfully removed by the knife, but it is best for the surgeon not to interfere. When *multiple subcutaneous fibrous tumours* are found upon a patient, one of them may be discovered beneath the skin of the scalp. Outgrowths from the skull, such as *exostoses* and *nodes*, must not be mistaken for scalp-diseases.

For *Nævus* of the scalp, see NÆVUS.

PULSATING TUMOURS OF THE SCALP.

1. *Aneurism* of a scalp-artery takes place after some injury—usually partial division of a vessel. It is rare, has the typical signs of aneurism, varies from the size of a pea to that of a bean, and can be cured by either pressure or excision.

2. The common seat of *cirsoid aneurism* is the scalp. It is formed by a congeries of dilated vessels, which pulsate with a loud systolic bruit. The skin over the tumour is hotter and thinner than elsewhere, and the unaltered cranial vault can be palpated through the worm-like mass of the tumour. See CIRROID ANEURISM.

3. *Hernia cerebri*. See BRAIN, Hernia of the.

4. *Encephalocele*. See MENINGOCELE.

5. *Sarcomata of the dura mater or cranium*, if rapidly growing, pulsate. The pulsation is not affected by compression of the arteries of the scalp, and pressure upon the tumour does not produce cerebral symptoms. The tumour is perfectly fixed, and evidently attached to or continuous with the bone. Egg-shell crackling may be present. The diagnosis can rarely be made at such an early period as to justify operative measures.

6. *Pulsating hæmatoma* containing cerebro-spinal fluid as well as blood. For a description of this form of pulsating tumour, see MENINGOCELE.

For cutaneous and parasitic affections of the scalp, *see* TINEA TONSURANS; PEDICULI; HORNS. CHARLES A. BALLANCE.

SCALPELS are small knives which are used for most surgical operations requiring dissection. There are three patterns of scalpels, which differ from one another slightly in the way the point is made. The common operating scalpel is sharpened on one edge only, and both edges are rounded off towards the point, so that the latter is in a line with the middle of the blade. In another pattern, the back of the scalpel is sharpened for about half an inch near the point; in a third, the cutting edge only is rounded off, and the back of the scalpel runs straight on into the point.

SCAPULA, Diseases of the.—A large variety of tumours is found connected with the scapula. By far the greater number start from the bone itself, and gradually involve the entire scapula, the muscles and soft structures attached to it, the shoulder-joint and clavicle, and are malignant. The ordinary growths, met with in other regions, present the same characters here as elsewhere.

FIBROMATA spring from the muscular or fascial tissues covering the scapula; they are firm in texture, slow of growth, generally lobulated, circumscribed and encapsuled, not often painful, and when removed, as a rule, do not return.

SARCOMATA.—These growths are either parosteal, in the tissues superficial to the bone, periosteal, or central, in their origin; the last form generally occurring in the medullary structure of the neck of the scapula, whilst the first two are usually associated with the body or borders of the bone. The diagnosis between the parosteal and periosteal forms is scarcely possible, as the former often so closely invest the bone that the mobility of the tumour underneath the muscles of the scapula is difficult to detect. Hence, it is not until the tumour has been cut down upon that any determination, as to the extent of the operative proceeding, can be arrived at. The parosteal form may be carefully removed from the bone, whilst the periosteal and central require excision of the scapula.

The *diagnosis* of these growths is always fairly easy. Generally, they have gained such hold, when the patient comes under observation, that the clavicle, and possibly the head or neck of the humerus, and the soft tissues of the head, neck, and axilla, are already involved. The growth

is usually well-defined; its surface possibly lobulated, and somewhat elastic on palpation; it is very rapid in development, and the subcutaneous veins are enlarged and prominent. There may or may not be pain; this must depend upon the invasion of the growth.

The sarcomata are most frequent in young subjects at about the age of puberty, and are possibly associated with some injury to the shoulder, although they often appear spontaneously. They are very malignant, and their growth and recurrence after removal are rapid, the latter occurring locally or in some viscus.

ENCHONDROMA is sometimes met with, springing either from the venter, dorsum, or, more frequently, one of the processes. It is uniformly firm in consistence, often nodular, painless, and of slow growth, although occasionally this is not the case.

GUMMATA are sometimes met with about the scapula. When occurring in the muscular structures, they may assume the appearance of real growth, and, as they are almost invariably of rapid development, may be mistaken for sarcoma. The history of the case will aid the diagnosis, and the exhibition of specific treatment in such cases of doubt is of the greatest value, the gumma speedily disappearing under its use. When gummata are situated superficially, they may simulate abscess.

ABSCESS may be either quite superficial or develop in the supra- or infra-spinous fossæ, beneath the fascia, as the result of injury, or spontaneously, unassociated with any disease of the scapulo-humeral articulation. It often commences as acute inflammation of some bursa, and the matter remains for a time pent up by the dense fasciæ, and eventually makes its way either towards the surface or into the axilla.

Subscapular abscess not infrequently occurs in the loose connective-tissue between the subscapularis and serratus magnus, and is most frequently a result of some lymphatic absorption, although it may occur spontaneously, and after some local injury. The ordinary symptoms of fluctuation—at first, at any rate—may be absent, as the collection of pus is so deep; but the high temperature, the throbbing pain, and the separation of the scapula from the thorax, together with the increasing inability to move the arm, and the gradual filling up of the axillary hollow, all point to the probability of abscess. An exploratory puncture should complete the diagnosis.

BURSAL TUMOURS.—The large bursa between the inferior angle and the thorax is

sometimes so enlarged as to present the appearance of a rapidly growing malignant tumour. It is usually noticed as the result of some over-strain or exertion, such as may be produced by rowing, cricket, or tennis. It appears as a tense, fluctuating tumour, pushing up the scapula and often encroaching on the axilla. If the growth be of long standing, its walls become much thickened, and it may be readily mistaken for a solid tumour. Occasionally, these enlarged bursæ contain melon-seed bodies, and on pressure or manipulation crepitus is detected; here, again, puncture with a trocar or aspirator reveals the nature of the swelling. Persons following particular trades develop bursæ over the scapula; thus bricklayers' labourers and porters frequently have an enlargement of the bursa immediately over the anterior edge of the trapezius. Such tumours occasionally suppurate.

PERIOSTITIS and OSTITIS, acute and chronic, are occasionally met with, and may be limited to certain portions of the bone or involve it entirely. They are sometimes due to struma or syphilis, occur spontaneously or as the result of exposure or injury, but more frequently are secondary to disease in the scapulo-humeral articulation or head of the humerus. The symptoms are much the same as in any other region; although, from the dense muscular and fascial coverings, the diagnosis is, at any rate in the early stages, not always easy. There is deep-seated pain referred to the bone itself, a rigor, and rise in temperature; swelling and cedema of the soft parts do not usually appear as rapidly as in the case of the more exposed and less embedded bones, but if the inflammatory attack be severe, suppuration is usually very rapid and diffuse. The resulting abscess points either in the axilla or in the supra- or infra-spinous fossæ.

NECROSIS of the scapula, either partial or entire, is generally the result of the above conditions, and when sinuses have formed, a probe will detect bare bone. The periosteum is very often detached entire, so that operative interference is comparatively easy when the diseased tissue is exposed.

DISPLACEMENT OF THE SCAPULA.—The peculiar condition, to which this term has been applied, is a displacement of the lower angle and spinal border of the scapula, whereby the bone seems to be lifted away from the thorax. It was formerly considered to be due to the scapula shifting from under the latissimus dorsi, but it is

now known to be the result of paralysis of the serratus magnus muscle, which may be partial or complete. The remarkable tilting up of the bone is due to the preponderance of power in the trapezius, levator anguli scapulæ, rhomboidei, and pectoralis minor.

The *diagnosis* is easy. If the arms are held forward, at right angles to the trunk, the elevation of the spinal border of the affected side is most marked, and the patient can project the sound arm about two inches further from the thorax than the affected one. The movements of rotation of the bone are either feeble or wanting on the affected side; in fact, the serratus magnus is incapable of performing its special functions.

Electricity seems the chief element in *treatment*; and Erichsen states that he has seen much benefit derived from the endermic application of strychnine on a blistered surface, followed by support by means of some properly devised apparatus.

EDWARD BELLAMY.

SCAPULA, Dislocations of the.—

Dislocations at the acromio-clavicular joint are sometimes described as dislocations of the acromial end of the clavicle, but they are more correctly classed as dislocations of the acromion process of the scapula. This may be displaced *downwards* or *upwards*.

DISLOCATION DOWNWARDS, though not a frequent injury, is far more common than dislocation upwards, and this is to be explained partly by the direction of the force, and partly by the direction of the articular facet, which on the acromion looks upwards and inwards. The injury is caused by a fall on the point of the shoulder, and the resulting deformity is easily recognised. The acromion process falls below its proper level, and the outer extremity of the clavicle rides upon it. The end of the clavicle forms a very distinct projection immediately beneath the skin, the nature of which it is scarcely possible to mistake. By drawing the shoulder well back and at the same time raising it slightly, the dislocation is easily reduced, but the deformity recurs immediately the support is removed; and thus, both in its tendency to relaxation, and in the extra mobility it occasions, this dislocation forms an exception to the rule. The difficulty of retaining the bone in position is so great that some have given it up as hopeless, and South recommended that no trouble should be taken, the clavicle being allowed to unite by fibrous tissue to the acromion, in its abnormal position. With great care and a tractable patient,

however, it is possible to obtain a cure without deformity. In other cases, the writer would suggest that it may be justifiable to excise the joint and wire the bones together; but it should be remembered that, if the bones are united in the dislocated position, the arm remains useful and but little weakened.

To reduce the dislocation, one hand should draw the shoulder well back, whilst the other is used to raise the elbow. To retain the bones in position, it is usual to place the arm in bandages similar to those used for fractured clavicle, but, in the writer's opinion, bandaging alone is wholly inefficient. He advises as follows:—A little absorbent cotton-wool, covered with zinc powder, should be placed in the axilla to prevent intertrigo; the arm should be carried forward so that the hand rests on the other clavicle, and the elbow be then forced upwards and outwards. Broad strips of Holland plaster (which does not stretch) should next be used to bind the arm to the side, and, to support the elbow and arm, strips should be carried over the opposite shoulder; a soft pad should be placed on the clavicle, and a broad strip of plaster be carried from the back over the pad and under the elbow. When the surgeon has tested the efficiency of the strapping, he should protect any prominences of bone with cotton-wool, and then cover the whole with plaster of Paris bandages. M. Laugier in eleven cases employed a tourniquet to keep down the clavicle. The arm should be fixed for six weeks.

DISLOCATION UPWARDS is very rare, and is caused by force applied to the upper surface of the clavicle. Besides rupture of the acromio-clavicular ligaments, the conoid and trapezoid give way. The rotundity of the shoulder is lost, and two bony projections appear, the upper and inner formed by the acromion, and the lower and outer by the end of the clavicle. The humerus rotates without difficulty, but the patient cannot raise his hand to his head. Reduction is accomplished by drawing the shoulder back, after which it is necessary to confine the arm to the side for five or six weeks.

Dislocation of the Coracoid Process upon the Clavicle was described in 1843 by Godemer, who related five cases as having come under his notice in five years, since which time M. Pinjon has added a sixth. Malgaigne throws doubt on the extraordinary experience of his compatriot, suggesting that both in the symptoms and in the effect of treatment the cases resemble

each other too closely to be all taken from nature. This dislocation must therefore be left for further experience to establish.

R. CLEMENT LUCAS.

SCAPULA, Excision of the.—This operation is indicated in cases of necrosis or of new growths. It is not without its difficulties, and these of course vary with the size or situation of the tumour; hence, any typical operation can scarcely be described. Such operations may be considered as (1) total resection or extirpation, in which the shoulder-joint is opened, and the glenoid cavity removed; (2) removal of the scapula, leaving the glenoid cavity and shoulder-joint, the neck being divided by a saw; and (3) resection of certain portions of the bone, especially of the spine, angles, or acromion process.

If it be necessary to remove the entire scapula, the most convenient method is as follows:—The subclavian artery being controlled by an assistant, and the arm extended from the side, an incision is to be made along the posterior border of the bone, and a second one along the spine, joining the first and terminating at the tip of the acromion. The triangular flaps so formed are next to be dissected off, thus exposing the mass to be removed. The muscles attached to the posterior border are then to be divided close to the bone, so as to allow of its being grasped by the hand and lifted off the thorax. The knife is then carried along the upper border, dividing all muscular attachments. The acromion process may be either disarticulated from the clavicle or cut through with forceps, or, what is preferable, the acromial end of the collar-bone divided. The muscular attachments along the axillary border should next be divided, and it is at this stage of the operation that the bleeding may be troublesome. The vessels should be clamped or tied as divided. The mass is then fairly free, and, being still further lifted up, the joint is next opened and the disarticulation effected, the remaining muscular attachments being divided, and the bone removed, the vessels ligatured or torsioned, and the flaps adjusted as in any ordinary amputation.

Subperiosteal resection is performed in cases of necrosis, and the bone being exposed by the above incisions, by means of rugines the periosteum may be stripped off; the attachments of the several muscles being preserved. There are several instances recorded of the entire scapula and its processes being removed subperiosteally with complete reproduction.

The actual operative proceeding is as follows:—An incision is made from the tip of the acromion to the base of the spinous process; a second incision is next to be made, commencing at the superior angle and following the spinal border of the scapula, terminating at the inferior angle. The incisions are carried through the periosteum. This membrane is first stripped off the acromion, next the spine, taking care to preserve the attachments of the deltoid and trapezius. The posterior border is then to be denuded, with the attachments of the rhomboidei. The periosteum should next be removed from the infraspinous fossa, and the infraspinatus and teres minor separated, followed by the detachment of the supraspinatus from its fossa. The articulation is next attacked on its posterior aspect, and the capsular ligament turned up from its attachment to the neck of the bone. The arm should now be extended, and the inferior angle of the scapula lifted up, and the bone thus tilted from within outwards. This exposes the subscapular fossa, and, on lifting the bone still further from the thorax, the anterior aspect of the capsule should be scraped off and opened. The bone should next be seized by strong forceps and twisted outwards. Such are the directions laid down by Ollier, as an exercise, presumably, on the cadaver, but in actual practice the separation of the periosteum, if not already complete pathologically, is of very easy performance, and has been practised with the most satisfactory results.

EDWARD BELLAMY.

SCAPULA, Fractures of the.—This bone is so movable, its processes are so strong, and it is for the most part so thickly covered with muscles, that it is very seldom broken. Its fractures are almost invariably due to direct and considerable violence; very rarely to muscular action. They are divided into those of (a) *the body*, (b) *the neck*, (c) *the acromion*, (d) *the coracoid process*.

FRACTURE OF THE BODY is caused by the passage of a wheel, by falls on the back upon a projecting stone or the like, or by a heavy blow. Though often transverse, its rays may extend upwards through the spine, or obliquely through its anterior or posterior border. It is often starred or comminuted.

Symptoms.—These are mobility of the fragments when the bone is grasped at different parts, or when the inferior angle is grasped, or the hand placed flat on the bone, while the arm is moved by an assistant;

accompanying crepitus, often a mere click, caught only on one particular movement. In fracture of the spine or of the borders, particularly in thin persons, displacement may be detected. In fractures below the spine, the lower fragment is generally found in front of the upper, and carried upwards, so that the bone is shortened from above downwards. But this is by no means constant.

Treatment.—Such readjustment as may be possible having been effected by manipulation, the scapula should be covered with a carefully moulded and well-padded gutta-percha shield for protection, and the arm fixed by bandaging in the position in which the fragments are found to be most easily maintained in place. Some deformity will probably remain, but this will usually not impair the functions of the arm.

FRACTURE OF THE NECK.—There appears to be no example in any museum of fracture of the anatomical neck of the scapula—that is, of a fracture detaching merely the glenoid cavity, and it may be very strongly doubted whether this injury ever occurs. There are, however, dissected specimens showing fracture through the surgical neck; that is, through the narrow part by which the glenoid cavity and coracoid process together are attached to the remainder of the bone.

Symptoms.—In this rare accident, always the result of a crush or other form of direct violence, the shoulder is somewhat flattened, as in dislocation of the humerus; the normal outline may be restored, and perhaps crepitus felt, when the elbow is raised; but deformity returns when the arm is allowed to hang down. The humerus is abnormally movable in all directions, and its head can be felt in the armpit. The patient is unable to raise the arm, and passive movement causes severe pain.

Treatment consists in placing a pad in the axilla; raising the arm, and supporting it by means of a firm sling acting on the elbow and forearm, and bandaging the arm to the side and the forearm across the chest. Movement, which is likely to be much impaired, may be improved by manipulating the limb, under an anæsthetic, at the end of six weeks, and subsequently employing passive movements, combined with hot douching and shampooing. Fracture of the margin of the glenoid cavity, or a stellate fracture of this cavity, is sometimes present as a complication of dislocation of the humerus. See SHOULDER-JOINT, Dislocations of the.

FRACTURE OF THE ACROMION is caused by falls on the shoulder or by a blow from above. The size of the fragment varies, and may include merely the tip or the whole process to the root of the spine. The injury is rare. Many supposed fractures with ligamentous union are instances of separation of the acromion, apparently at the line of junction of the epiphysis with the rest of the bone, in the course of rheumatic arthritis. In St. Bartholomew's Hospital Museum is a specimen of this kind, in which the acromion is divided into two pieces, one of which is still connected with the spine by a very narrow bridge of bone, the other, at the tip, being joined to the first piece by fibrous tissue.

Symptoms are dropping and flattening of the shoulder, pain, loss of power to raise the arm, displacement, and the rough edge of the fracture felt on passing the finger along the bone. The deformity is removed by elevating the arm—when probably crepitus can be felt—but returns when the arm is allowed to hang down.

Treatment.—A pad having been placed in the axilla, the arm must be supported in a sling, and bandaged across the chest, as in fractured clavicle. Union is generally fibrous, but there is slight if any impairment of the functions of the limb. Bony union might probably be secured by confining the patient to bed, and raising the arm, so that dragging on the fragment might be prevented.

FRACTURE OF THE CORACOID PROCESS,
see CORACOID PROCESS, Fracture of the.
HOWARD MARSH.

SCARIFICATION.—A method of local blood-letting, extremely limited in scope and generally of doubtful utility.

The operation consists merely in making a number of small, very superficial cuts, which may be crossed by others, and allowing the blood to ooze from them.

It is sometimes recommended in conjunctival chemosis, in the early stages of acute tonsillitis, in cedema and engorgement about the glottis, and in certain conditions of the os uteri. On the skin it is useless.
WILLIAM H. BENNETT.

SCHIZOMYCETES.—*Synon.* Bacteria, bacteridæ, vibrios, schistomycetes, micro-organisms, microbes, microzymes, cocco-bacteria.

Schizomycetes is the classical name, now in general use, to express the whole class of micro-organisms formerly known indefinitely as bacteria, that term being now

restricted to one genus. It signifies the fact that organisms of this class reproduce themselves by fission of the parent organism, and this is the case with all species, though not the only method in several.

This class of organisms was arranged by Cohn in the following order of genera, which has been found to be by far the most practical:—

MORPHOLOGY.—*A. Coccus* forms.—Spherical or oval organisms; subdivided by Billroth into micrococcus and megacoccus. *See* MICROCOCCUS.

B. Bacterium (q.v.).—A short, oval, or cylindrical rod-shaped organism, with rounded ends, or also an ellipsoidal shape constricted in the middle like a biscuit (clithridium). In any case the length of the organism does not exceed twice its breadth.

Varieties of bacterium are frequently provided with a flagellum.

C. Bacillus (q.v.).—Rod-shaped organisms, in which the length of the adult element is much greater than its breadth. This is perhaps the most important genus.

D. Vibrio (q.v.) is practically a curved bacillus, the curves (1-2 in number) being always in the same plane.

E. Spirillum (q.v.) is a spiral-shaped thread, which when greatly overgrown has received the name spirochæta, these latter forms being also more flexible.

Habitat.—These organisms are found in varying quantities in the air, in water, and in the soil. The quantity in the air of temperate climates varies according to the height from the earth, to the action of the wind in raising dust, and temperature—i.e. according to the season of the year. Some species attack and inhabit the interstices of living animal tissues, while very many exist as parasites on the cutaneous and mucous surfaces of the body.

Structure.—All the schizomycetes consist of a protoplasmic body, containing small fat and sulphur particles, and staining readily with anilin dyes. This protoplasmic body or core is surrounded by a sheath, which possesses many characters of cellulose, and offers powerful resistance to many chemical reagents. The protoplasm is an albuminous substance, the basis of which is an albuminoid compound termed mycoprotein, which contains no combined sulphur. In several species the protoplasm is pigmented, the prevailing colours being yellow, orange, red, and blue.

LIFE CHANGES.—*Respiratory.*—All forms require oxygen, and give out carbonic acid. Most need free oxygen, and there-

fore are termed aerobic; others can probably take the oxygen from combination, and hence have been termed anaerobic; but this division is not satisfactory. In some (bacilli), the growth when exposed to free oxygen tends to spore-formation.

Thermic.—All forms grow best at about 36° C. (96·8° F.). All adult forms are killed at 50° C. (122° F.) moist heat, and by severe cold. Spores, however, survive much greater extremes, viz. 120° C. (248° F.) dry heat.

Very few forms can grow in pabulum which is kept in rapid motion (e.g. blood, &c.). Light appears slightly to retard growth, and electricity also, but this latter probably by electrolysis of the pabulum.

Chemical.—These organisms split up both simple and complex substances to gain the necessary elements for their nutrition. They require hydrogen, nitrogen, oxygen, and carbon, while at the same time it is essential that there should be a trace of phosphate in the nutrient fluid. As results of the catalytic action of their life, fats, albuminoids, and carbohydrates are broken up in a way that can be imitated by the action of superheated steam and potash, so that it is probably a process of hydration. Thus, fats become rancid from the development of butyric acid, &c.; the carbohydrates and glycerine are decomposed into alcohol, butyric and carbonic acids; albumins are broken up into glycocoll, leucin, tyrosin, and aromatic compounds, while the former again are resolved into ammonias and lower acids.

On living tissues the schizomycetes appear to exert a progressive necrotic action, partly due to their breaking up the tissue for nutrition, and partly, perhaps, to the effect upon the healthy tissue of the products of such decomposition. See SEPSIS; SEPTIC DISEASES, Classification and Etiology of.

REPRODUCTION.—This is effected either by fission or spores.

(a) *Fission.*—According to the elevation or depression of the surrounding temperature, an adult organism will quickly or slowly divide into two, usually first elongating, but in rapid subdivision the daughter elements are very short, so that the primary elongation is slight. In the rod forms, the subdivision is always at right angles to the direction of the long axis. In the coccus forms, the subdivision takes place in every direction, and thus sarcinoid groups of four or more result. *Vibrio* forms appear to possess the power of vacuolating and then dividing longitudinally

(Klein). When organisms grow rapidly by fission, they form masses termed zoogloea, the individual organisms composing which are held together by an albuminous substance, which sometimes forms a gelatinous envelope.

(b) *Spores.*—In the presence of free oxygen, many bacilli tend to grow into long threads (leptothrix), in the interior of which there develop brightly refracting spots which by atrophy of the rest of their filamentous sheath become free, as oval protoplasmic masses surrounded by a very resisting sheath. A similar process of spore-formation may be seen in adult rods. These bodies are spores, and, under suitable conditions, will elongate and develop into single rods. They possess fully three times the power of resisting destruction by heat, chemical reagents, &c., that the adult rods do, and, consequently, play an extremely important part in the etiology of diseases such as malignant pustule, &c.

Practical Importance.—The practical importance, to the surgeon, of the existence and life-processes of these parasitic organisms cannot perhaps be exaggerated; but since this point involves the question of fermentation and etiology of infective diseases, it is fully described in the article on SEPTIC DISEASES, and need not be repeated here. The treatment of the different conditions, with which micro-organisms are actively concerned, will also be found under the various septic diseases.

VICTOR HORSLEY.

SCIATIC HERNIA.—This form of rupture is very rare. The protrusion escapes through the great sacro-sciatic foramen. The fundus of the sac is found beneath the gluteus maximus muscle; the neck may be either above or below the pyriformis, and will be in front of the gluteal artery, and below the obturator. Sir Astley Cooper has reported a case where a piece of ileum was strangulated in this position. The hernia was not discovered until after death. The hernial orifice could be readily examined by introducing the hand into the rectum.

FREDERICK TREVES.

SCIRRHUS. See CARCINOMA; BREAST, Diseases of the.

SCLEREMA NEONATORUM.—*Definition.*—An induration of the skin, with lowered temperature, occurring congenitally or soon after birth. Until Parrot distinguished between the two affections, sclerema and oedema neonatorum were mixed up together.

Etiology.—Sclerema may be primary or secondary. The primary cases are either congenital, or occur in a very few days after birth, without apparent cause. The secondary cases are the sequel of causes which depress vitality, such as diarrhoea or pulmonary affections, like pneumonia, with collapse or atelectasis; it is apt to occur with malnutrition from bad feeding and defective hygiene. Œdema happens, almost invariably, in infants which are premature or of otherwise feeble vitality, and there, too, atelectasis is frequent; bad feeding of mother and child, or exposure to cold immediately after birth, are also causes.

Pathology.—Langer considers the first condition a 'fat sclerema'—i.e. due to solidification of the fat; infantile fat having a much higher melting point than adult fat. On the other hand, Parrot regards it as a consequence of desiccation of the tissues from the drain of diarrhoea, &c.

Œdema is presumably due to the feeble circulation and defective aëration of the blood at a period when vital resistance is always small.

Symptoms.—When not congenital, the induration generally begins in the lower limbs—rarely in the face—within ten days of birth, spreads to the trunk, and is usually complete over the whole body-surface by the fourth day from its commencement; but it may remain incomplete. At first, the skin is of a yellowish-white or waxy appearance, but it soon gives way to a slightly livid tint, and the skin becoming adherent to the subjacent tissues as well as rigid, it cannot be pinched up, and there is no pitting on pressure. The skin is tense, smooth, cold, and hard. The limbs and jaw are fixed, the eyes closed, and the child lies motionless with the exception of slight movements of the thorax and face, the latter being less rigid than other parts; but the stiffness of the lids and cheeks prevents sucking, the pulse, respiration, and temperature sink far below the normal, and life is completely extinguished within a week.

Œdema begins in the third day of life, with drowsiness, swelling of the extremities, especially of the legs, which pit on firm and prolonged pressure, and are cold and livid. The œdema spreads up to the thighs, then to the hands, the genitals, and back; the soles and pubes are especially affected, and are red and hard, sometimes doughy. The drowsiness increases, the pulse gets feeble, the respiration slow and shallow, and complications, such as pulmonary af-

fections, with collapse, diarrhoea, or convulsions, hasten the fatal issue; jaundice sometimes supervenes just before death. Recovery takes place in some cases, if they come early under treatment.

Diagnosis.—Though so much alike in etiology, and in the depression of the vital processes, these two affections may be distinguished by the following points:—

In sclerema, the disease is general; the skin, tense, hard, and waxy in colour, does not pit, and cannot be pinched up.

In œdema, the disease is less widely spread, the skin is livid from the first, not so hard as sclerema, pits on firm pressure, and can be pinched up, while the swelling is always greatest at the lowest parts. In sclerema the joints and jaw are stiff; not so in œdema, or only in a slight degree.

The onset so soon after birth is alone sufficient to distinguish both forms from scleroderma, in which no case under two years has been recorded.

Prognosis.—Death invariably ensues in a few days, when the induration is universal; but in the rare, incomplete cases recovery may be hoped for. In œdema the prospect is not quite so hopeless, though always serious, and the cases last longer.

Treatment.—Efforts must be made to keep up the temperature; the child should therefore be wrapped in cotton-wool, and surrounded by hot-water bottles; friction of the limbs with oil is also a useful measure. As the child cannot suck, food must be introduced into the stomach by a small stomach-pump tube passed through the nose, or by Battam's plan of attaching an india-rubber tube to the nozzle of a glass syringe, passing it into the pharynx, and then injecting the food; peptonised milk and white-wine whey are suitable aliments, for digestion, like the other functions, is at its lowest ebb.

H. RADCLIFFE CROCKER.

SCLERODERMA, or hide-bound disease.

Definition.—A subacute or chronic disease, characterised by extreme induration and rigidity of the skin.

This disease is a rare one, and has nothing in common with sclerema neonatorum, except the hardness of the skin, which is due to a different cause. There are three classes of cases: one in which the skin-affection is diffuse and symmetrical, another in which it is circumscribed, and a third or mixed class which partakes of the characters of both the other forms. The first two require, to some extent, separate con-

sideration, as the symptoms and etiology are in many respects very different.

Etiology.—Females are much more prone to this disease than males, in the proportion of three to one in the case of diffuse, and a still larger proportion in circumscribed scleroderma. It may occur at all ages from two years and upwards, but is most frequent in young and middle-aged adults. In diffuse scleroderma, previous attacks of acute rheumatism and erysipelas are the most frequent remote antecedents, and exposure to wet or cold is the most frequent exciting cause. Cases that follow from definite conditions are generally acute in their onset; while, frequently, no cause can be traced for those which are slow and insidious in their development; and, in many instances, the patient has been in good health until attacked with scleroderma.

The cause of the circumscribed form is quite obscure. In many there is a history of worry, anxiety, or other depressing mental influence antecedent to the appearance of the patches; in a few, chiefly band cases, local irritation or injury appeared to be the exciting cause; whilst the rest seemed to be spontaneous in their development.

DIFFUSE SYMMETRICAL SCLERODERMA.
Symptoms.—These cases are seen in two phases: one where the skin is swollen, the other where it is shrunken. The first is usually, but incorrectly, ascribed to hypertrophy, but is really due to infiltration; and the shrunken state is one of atrophy. The swollen stage is the early condition, and may be quite hard from the first, or stiffly œdematous; and the shrunken stage is a sequel to the œdematous variety.

The common history is that the disease came on after exposure to cold or wet, arthritic pains and perhaps the symptoms of subacute rheumatism sometimes attending the onset; or there may be no other symptoms except those of the skin. A feeling of stiffness of the skin is first experienced, hindering movement, and attended by a sense of tension; and the affected part becomes quite hard, rigid, and cannot be pinched up. This symptom may come on quite suddenly, or so slowly and insidiously that the patient is scarcely aware of its commencement.

The upper half of the body is most frequently attacked, the stiffness being first felt in the back of the neck, the chest, shoulders, or arms. Once started, the process may spread slowly or rapidly over a large area, or even over the whole body-surface;

but the lower half is never attacked without the upper being involved, though the converse often happens. Whatever be the extent—and the disease is often very erratic in its distribution—symmetry is preserved. The palms and soles are rarely involved, but any of the mucous membranes may be affected. The edge of the affected area merges imperceptibly into the surrounding skin, while the affected part is extremely tense, and, when the parts beneath are affected, the muscles feel as if rigor mortis had set in. No pitting can be produced on pressure, and no fold can be pinched up; the surface is pale and marbled by dilated small vessels, and sometimes pigmented to a varying extent. If the face is involved, the features are as fixed as those of a statue, and when the trunk is attacked, respiration is interfered with; while in the limbs the joints are immovable and more or less flexed from contraction of the distended skin.

There is no alteration in the sensibility, but itching is sometimes troublesome, and sweating is more or less in abeyance. Subcutaneous tubercles, like rheumatic nodules, have been observed in a few instances.

In the œdematous cases, instead of induration a stiff œdema is present at the commencement, and the real nature of the disease may be unsuspected at first. After lasting some weeks or months, the œdema gets absorbed, the skin shrinks, acquires a dead or ivory-white hue, and the atrophic stage is developed. This atrophic condition is usually less widely spread than the œdema which preceded it, and is often confined to the limbs and face, but the symmetry is retained. The skin is now as tense as before, but from contraction, not distension; in the face the skin is strained over the bones, and may be directly adherent to the periosteum from compression-atrophy of the fat and muscles; the lips are drawn up, the gums retracted, and the teeth in extreme cases fall out. The countenance is bloodless, except where mottled by telangiectases, and the fixed features and straining of the skin over the bones give a ghastly corpse-like aspect; the limbs of an adult may be reduced to the size of a child's, the joints ankylosed, and the hand claw-like. In consequence of the tension of the skin over the joints, ulcerations, sometimes attended with necrosis, easily ensue from slight injuries.

The course taken by these two forms varies somewhat; the tensely infiltrated cases tend to clear up sooner or later, the infiltration is gradually absorbed, the skin

becomes less rigid, and after some months, but in some cases not for years, the skin gradually regains its normal softness and elasticity. Some think that these cases may also merge into the atrophic form, but this is not the opinion of the writer. Progress may be interrupted if the patient get a chill, and even extension may then ensue, and, according to patients' statements, the skin is tighter on some days than others. In the contracted cases recovery is less frequent, the disease often remains stationary for years, or it may extend at long intervals. The general nutrition suffers, and the patient gradually sinks or dies from intercurrent disease. It is a long time, however, before the general health suffers, and many seem to be little the worse except from their helplessness.

No special complications, except rheumatism and valvular heart-affections, are found associated with this disease, but other eruptions may be present, and filaria sanguinis hominis has been twice found.

CIRCUMSCRIBED SCLERODERMA, or MORPHEA, is, by some authors, still regarded as an entirely independent disease; but the other view gains ground, and will doubtless eventually prevail.

Symptoms.—It occurs in patches and bands, the former being the most common. The patches, which may be single or multiple, are usually from half to two inches or more in diameter, situated generally on one side of the body, often in the course of a nerve, like herpes zoster, but sometimes in the middle line, sometimes bilaterally, and occasionally symmetrically. They develop gradually, rarely rapidly, without any symptoms. The domain of the fifth nerve, the breasts, and still more frequently the limbs, are favourite positions, but they may come anywhere.

The majority of the patches are of an ivory-white colour, smooth and dry, surrounded by a pink or violet zone of minute dilated vessels; but this zone may be absent, and the patch more or less pigmented in various hues. The edge may be diffused or defined, its shape is as irregular as its size; it may be raised above (*M. tuberosa*), depressed below, or level with the surrounding skin. No difficulty is usually experienced in pinching up the diseased skin, and as it is rarely adherent to the subjacent tissues, and is quite superficial, it feels like parchment or leather, according to its thickness, which varies often in the same patch. As a rule, when once it is developed there is no increase in size, but sometimes small atrophic spots appear

close to the major patch, enlarge, and coalesce with it.

Defects of sensibility are rare, but there is itching in some cases. In the band cases, the lesion is usually single, and, unlike the patches, is often adherent to the subjacent tissues, so that it is sunk into a sulcus below the healthy skin; but if non-adherent it may be raised up into a ridge.

Pathology.—The pathology of this affection is obscure, but the process does not appear to be inflammatory, and the theory most in accordance with the clinical facts is that of an obstruction of the arterial blood-supply to the skin, on the one hand, and the venous and lymph flow on the other; and the varying symptoms of different cases depend upon the relative degree of obstruction in one or other of these vascular systems. But what the primary defect is that brings this about is not known, and it must be inferred that it is of central nervous origin, and in fact that the disease is primarily a central tropho- or vasomotor-neurosis. Diffuse scleroderma has been anatomically examined by many, and the results, omitting minor differences, are as follows:—The changes are, in the main, in the deeper parts of the corium and subjacent tissues, and consist of narrowing of the lumen of the blood-vessels and accumulation of cells round them.

Later on there is destruction of the sweat and sebaceous glands and hair-follicles, and absorption of the fat and cellular tissue by the pressure of these cells, and a great development of connective and elastic tissue bundles, doubtless from fibrillation of the cells; and the skin may become directly adherent to the fascia or periosteum.

The anatomy of circumscribed scleroderma has been examined by the writer. The changes were of very similar character to those of the diffuse form, but were more superficial, affecting the upper part only of the corium, in the early stage; and thrombi were present in many of the vessels, explaining the pallor and thinning present at first. At a later stage there was increase of the connective tissue, and the changes had spread into the deep part of the corium and into the fat layer. In the opinion of the writer, the obstruction to the arterial blood-supply is greater than in diffuse scleroderma, and so atrophic changes are more often produced. Probably the nervous defect is not central, affecting perhaps only single nerves in this class of cases.

Diagnosis.—The wooden induration and immobility of the skin and subcutaneous tissues, occurring symmetrically over a wide

area, with or without the ivory colour super-vening, are conditions almost peculiar to diffuse scleroderma, with the sole exception of sclerema of the newborn, in which there is induration with great coldness of the surface; this, and the age of the patient, would be obvious distinctions. There remains only one disease, even rarer than scleroderma, which may give rise to some doubt—namely, diffuse primary or secondary cancer of the skin—the '*Cancer en cuirasse*' of Velpeau. If secondary, it often begins with nodules; this and the previous history would remove all doubt, but in the primary cases there may be more difficulty. The slow, continuous spreading, the lancinating pains and tenderness, the neighbouring inflammatory cedema, the ulceration of the lesions and involvement of the glands, with the more rapid course of marasmus and fatal cachexia, are all points in which it differs from scleroderma.

Circumscribed scleroderma presents even less difficulty. The raised patches might perhaps be mistaken for the keloid of Alibert, but the difference in colour, the ivory-white tint of morphœa being absent, and the presence of vessels upon the tubercle, and the claw-like processes which extend from it, would distinguish this affection. The flat patches are quite distinctive, and no confusion could arise with ordinary care.

Treatment.—In the diffuse form, the indications are to guard the patient against cold, since aggravation and extension are very likely to follow a chill, to which the patients are abnormally prone; secondly, to improve the general nutrition; and thirdly, to restore the circulation in the ischæmic area. For the first, the patient should be clothed in flannel, never allowed to go out in cold winds, and guarded carefully against draughts.

For the second, ferruginous and other tonics suitable to the individual should be given, and cod-liver oil is often very beneficial. The digestive organs should be carefully attended to, since they partake often in the general enfeeblement, and flatulence aggravates the distressing tension when the trunk is affected.

For the third, shampooing should be systematically and diligently employed to the affected areas. Turkish baths are useful before the rubbing, but vapour baths are too depressing.

Where Turkish baths are not available, inunctions with neat's-foot or olive oil, or simple unguents are useful; galvanism is strongly recommended by some, and may

be of service, probably, by improving the circulation.

Iodide of potassium, arsenic, and mercury have been repeatedly tried and found useless, and mercurial inunctions have been decidedly injurious in many cases.

The treatment of morphœa is very unsatisfactory; nothing has any direct effect for good, and anything producing local irritation aggravates the mischief. General invigorating measures are useful, and nerve-tonics, such as the mineral acids and nuxvomica, are often indicated. Galvanism has been recommended, but must be used so as not to irritate the patch; but if employed in the neighbourhood may be beneficial. Inunction may also be tried with simple ointments, always remembering that, if not worried by injudicious treatment, the patches tend to get well of themselves eventually. Mercury, internally or externally, should be avoided. The mixed cases should be treated in the same way as diffuse symmetrical cases.

H. RADCLIFFE CROCKER.

SCLEROSIS. See INDURATION.

SCLEROTIC, Diseases of the.—*Anatomy.*—The sclerotic is the white, tough fibrous membrane which constitutes five-sixths of the outer coat of the eyeball. In front, it is continuous with the transparent cornea; behind, with the sheaths of the optic nerve and with the connective tissue investing the fasciculi of the nerve (*lamina cribrosa*). That portion of it which may be seen within the opened eyelids, through the semi-transparent conjunctiva, is called 'the white of the eye.' Externally, it is smooth, except where the tendons of the muscles are inserted, and is enclosed by a thin fibrous covering—the episclera—lined with endothelial cells. This covering—the so-called 'capsule of Tenon'—which also furnishes the sheaths to the straight and the oblique muscles, is very loosely attached to the sclerotic, except in front, where, at about one-eighth of an inch from the periphery of the cornea, it becomes intimately blended with both the conjunctiva and the sclerotic, and cannot be separated from either without laceration. The sclerotic is lined by endothelial cells containing more or less pigment, and is loosely connected with the underlying choroid by many delicate connective-tissue fibres, nerves, and blood-vessels. It is chiefly composed of bundles of fine fibrillæ, among which a few elastic fibres are scattered. The bundles of fibrillæ are irregularly arranged into

layers, which interlace at various angles. Most of the bundles have either a circular or an antero-posterior direction, and a smaller number are disposed obliquely. Around the entrance of the optic nerve, as well as near the cornea, the circular bundles predominate. Among and between the layers is a system of lymphatic channels with spaces containing fixed cells, closely resembling those of the cornea. Most of the cells are unpigmented, but a few are pigmented. The latter are found chiefly around the entrance of the optic nerve, and in the deeper layers of the sclerotic near the cornea. In negroes and dark races generally, the proportion of pigmented cells is always greater. Migratory cells also circulate in the lymphatic channels.

The sclerotic has comparatively few blood-vessels and nerves. It receives a few small branches from all the ciliary arteries and veins. These vessels form a wide-meshed plexus, chiefly on the surface, in which, as a rule, two veins accompany each artery (Leber). On the anterior surface, around the margin of the cornea, the distribution of the blood-vessels is peculiar. At about one-twelfth to one-eighth of an inch from the cornea, the anterior ciliary arteries, which are the terminations of those supplying the straight muscles, divide into—(a) perforating branches, which pass through the sclerotic to go to the ciliary body, where they join the posterior ciliary arteries, and (b) superficial branches, which lie in the episcleral tissue and anastomose by arched communications in the neighbourhood of the corneal margin. The latter are called episcleral arteries. From these arcades two sets of branches arise—one consisting of small straight vessels which run up to and within the limbus of the cornea, and form with the subjacent episcleral veins the marginal vascular plexus of the cornea; the other consisting of vessels which bend backwards, to end in the conjunctiva and anastomose with the posterior conjunctival vessels. The circumcorneal vascular plexus or ring is therefore made up of episcleral and the anterior conjunctival vessels, which freely communicate with each other, and are directly connected with the vessels supplying the anterior portion of the conjunctiva, the sclerotic, the cornea, the ciliary, and the iris. Hence, in inflammation affecting these parts, the marginal plexus, which in health is almost invisible, becomes more or less conspicuous, forming what is generally called 'the zone of ciliary injection.'

Pathology.—Containing few blood-vessels, nerves, cells, and lymphatics, and

subservient only the functions of an exoskeleton, the sclerotic is a comparatively indifferent structure; its composition is stable, its nutritive processes are sluggish and not easily diverted. Consequently, it is but little susceptible of disturbing influences, and is subject to few pathological changes. Indeed, when these changes do occur, they are generally associated with and dependent upon morbid states of one or more of the adjacent textures—namely, the ciliary body, the choroid, or the iris, or, much more rarely, the cornea.

It is at first sight remarkable that, notwithstanding the unbroken structural continuity, the sclerotic proper is seldom much affected in inflammation of the cornea; though it readily participates in inflammation of the iris and ciliary body, to which it is contiguous only. The explanation seems to be, that the nutrition of the cornea is, in the main, distinct from that of the sclerotic, and that both these structures are alike primarily dependent upon the integrity of the ciliary body for their organic maintenance.

The commonest inflammatory manifestation, referable to the sclerotic, is now known to involve rather the episcleral tissue than the substance of the sclerotic. The morbid state is still, however, often spoken of indiscriminately as scleritis or scleritis and episcleritis. The truth is that though episcleritis may occur alone, it is not infrequently associated with inflammation of the sclerotic. The concurrence is to be accounted for partly by the nature of the inflammation and its exciting cause, but chiefly by the anatomical peculiarities of its situation. From what has been already stated respecting the relations of the episcleral capsule and the sclerotic, it will easily be understood that the further the focus of disease from the cornea, the less likelihood of a concurrence of scleritis and episcleritis, and *vice versa*. Near the cornea, the union between the two is so close and intimate as to come near to identity of structure, while at a distance the connection is both slight and readily separable.

Nosology.—The principal morbid states of the sclerotic and episclera are:—Hyperæmia, episcleritis, scleritis, staphyloma, and tumours; they are also subject to some slight congenital abnormalities.

HYPERÆMIA.—Hyperæmia of the scleral and episcleral vessels is usually indicative of a morbid state of the cornea, iris, ciliary body, or choroid; or it may signify obstruction to the intraocular circulation, due either

to increased intraocular pressure, or to some other cause. It occurs in two forms—(a) as a pink or, more commonly, a purplish zone, patch, or crescent, at the margin of the cornea; and (b) as large varicose vessels running over the surface of the sclerotic, from about the margin of the cornea towards one or other of the straight muscles.

(a) The former is the more frequent form. Typically, it consists of a purplish zone, varying in breadth from one-eighth to one-fifth of an inch, immediately surrounding the cornea. On examining this zone more closely, it will be found to be made up of the minute radiating blood-vessels described above by the name of *episcleral vessels*. In some cases the injection does not entirely surround the cornea. With the redness there is usually some swelling, due partly to the engorgement of the blood-vessels, and partly to infiltration of the episcleral tissue. The conjunctiva with its vessels may, by gentle pressure and friction upon the edge of one or other lid, be made to glide over the enlarged vessels, which obviously lie upon the surface of the sclerotic. If the conjunctiva also be inflamed, the scleral and episcleral vessels may be masked to some extent by the congested conjunctival vessels, which are distinguishable by their reticular arrangement, and by being largest and most conspicuous towards the lacunar portion of the conjunctival sac.

(b) The varicose state of the scleral vessels is most frequently met with in chronic inflammation of the sclerotic, iris, ciliary body, or choroid, and is generally present in glaucomatous eyes. It may, however, be due to pressure or other disturbances behind the eyeball, either within the orbit or beyond it.

EPISCLERITIS is an inflammation of the loose fibrous covering of the sclerotic. The inflammation may be strictly limited to the episcleral tissue, or it may involve likewise the conjunctiva on the one hand and the sclerotic on the other, or both these structures may be concurrently implicated.

Objectively, episcleritis consists of a more or less circumscribed dusky-red or purplish swelling on 'the white of the eye,' under the conjunctiva, and near the cornea, or within one-third of an inch of it. The most frequent seats are near the corneal limbus, and opposite the insertion of one of the recti tendons, especially the external. The vessels of the overlying conjunctiva are generally enlarged, but the mucous membrane itself is, in the earlier stages at least, freely movable over the swelling.

When the swelling is close to the edge of the cornea, the adjacent portion of the cornea becomes hazy from infiltration into its layers and from disturbance of the epithelium. Eventually, the affected area of the cornea may ulcerate. The sclerotic itself rarely if ever ulcerates in true episcleritis. In some cases, iritis complicates episcleritis; and, more rarely, there is cyclitis.

The *subjective* symptoms are variable. The pain is not usually severe, and does not amount to more than a sense of discomfort, with, perhaps, a dull aching sensation when the eyeball is moved or the eye is used for near work. On the other hand, there is sometimes great pain of a neuralgic character, not only in the globe, but also around the orbit and down the side of the nose. In these cases, however, it will generally be found that there is, in addition to the episcleritis, inflammation of the cornea, or the iris, or even the ciliary body itself. Nor is the sight affected, unless one or other of these parts be implicated.

The *course* of the disease is very chronic. As swelling leaves one part, it may reappear in another, and in this way the case may be prolonged for months. The average duration is about from two to four months.

Termination.—The inflammation may disappear without leaving any traces behind it, or at most only some thickening of the episcleral tissue. In a few cases, a faint discoloured patch persists on the surface of the sclerotic. But if the cornea have been involved, a nebula or actual leucoma may remain.

Clinical Varieties.—At least four distinct varieties of episcleritis may be met with—namely, (1) a circumscribed, indolent, purplish swelling appears opposite the insertion of one of the recti tendons and under the conjunctiva. There is little or no pain, watering, or distress of light. This form may occur during an attack of acute rheumatism, and it is probably always associated with the rheumatic diathesis.

(2) The episcleral swelling is not so circumscribed, and is situated near to the cornea. The conjunctival vessels are enlarged, and there is a patch, or may be, zone of injection at the margin of the cornea. There is also congestion of the iris, as evidenced by a small amount of discoloration and a semi-contracted state of the pupil. The eye waters, cannot bear exposure to light or to cold and damp air. The pain is often very great, both in the eyeball and in the brow. Such cases were formerly spoken of as examples of catarrho-rheu-

matic ophthalmia (Mackenzie). In some cases actual iritis may occur.

(3) Episcleritis may complicate, or be complicated, by phlyctenular ophthalmia. In chronic or recurrent marginal phlyctenular keratitis, the inflammation may extend to the episcleral tissue, and in some cases, following the course of the vessels, it may spread thence through the sclerotic to the ciliary body and iris.

(4) An episcleral infiltration-patch forms near the corneal margin. In a few days the adjoining portion of the cornea is seen to be hazy and its epithelium roughened, and, in the course of one week or more, the infiltration-patch may gradually desert the episclera altogether, to invade the cornea. The softened cornea may then disintegrate and a deep ulcer result. The ulcer, too, often assumes a serpiginous character, and spreads along the margin of the cornea and over the surface; or, running down to the posterior elastic membrane, leads to bulging of the posterior elastic membrane, with prolapse of the iris and ultimate perforation. This form is chiefly met with in anæmic and debilitated persons, especially women weakened through suckling or exhausting illnesses. There may not be much pain in this form, though there is usually great distress of light. The serpiginous form of episcleritis is probably neuropathic. In most of the cases which have come under the writer's observation, there have been other evidences of faulty innervation.

Causes.—Episcleritis occurs chiefly in young and middle-aged adults, rarely in children or in old persons, and it is more frequent in women than in men. The common exciting causes seem to be rheumatism, gout, syphilis, and scrofula. It is sometimes associated with uterine disease, catamenial disorders, and occurs during pregnancy or after parturition.

Treatment.—The local treatment should be soothing. Irritants of every kind are contraindicated. In recent cases, moist warmth, as steam-spray fomentations, is generally agreeable and useful. Sometimes, however, moist warmth increases the pain. In any case, glycerine of belladonna, or weak mercurial ointment containing extract of belladonna, may be applied with gentle friction to the brow or temple, and a solution of atropine may be applied to the conjunctiva, and repeated if found not to irritate. Pain is generally relieved and the duration of the disease shortened by systematic diaphoresis, whether induced by Turkish or other hot baths, draughts or

subcutaneous injections of pilocarpine, or in any other way. Sulphate of quinine, with small doses of calomel (gr. $\frac{1}{4}$ to gr. $\frac{1}{2}$ three times a day), seems, in many cases, to promote the absorption of the inflammatory matters. De Wecker speaks highly of the combination of copious sweatings with the internal administration of salicylate of soda. In chronic cases, blisters may be applied every ten days to the temples, and astringent compresses every night to the closed eyelids. In chronic cases, with opacity of the cornea, *massage* of the eye repeated many times a day has been recommended by Pagenstecher. If there be inflammation or ulceration of the cornea, with a deep anterior chamber and increased intraocular tension, sclerotomy may be tried and repeated at discretion.

SCLEROTITIS.—Idiopathic scleritis seldom, if ever, occurs; inflammation of the sclerotic being generally secondary to iritis, or cyclitis, or choroiditis. See CHOROID, CILIARY BODY, IRIS, Diseases of the.

STAPHYLOMA OF THE SCLEROTIC is comparatively rare, and is the result either of injury with laceration or of inflammation of some portion of the uveal tract.

The common situations are—the corneo-scleral margin, the ciliary region, the equator, and the posterior pole, just outside the optic nerve.

NEW GROWTHS are very rare, so-called tumours of the sclerotic being really growths which have invaded the sclerotic rather than originated in it. Still, fibrous growths and sarcomata do sometimes occur.

Treatment will depend upon the nature of the growth. Malignant tumours cannot be removed too early, even though the eye be certainly sacrificed by the operation. See ORBIT, Tumours of the.

JOHN TWEEDY.

SCLEROTIC, Injuries of the.—The sclerotic is liable to all and any of the injuries which affect soft parts—namely, blows and concussions, contusions, wounds, ruptures, burns, scalds, the effects of corrosives, and other chemical irritants and caustics.

BLOWS, CONCUSSIONS, or CONTUSIONS may be *simple*—that is, affect only the sclerotic—or *complicated* by injury to the adjacent parts. The principal complications are, contusion or wound of the lids or the cornea; subconjunctival ecchymosis; paralysis of one or more of the recti muscles; detachment or laceration of the choroid, iris, retina, suspensory ligament, or the capsule of the lens; hæmorrhage into the anterior chamber, the vitreous, behind the retina or

the choroid; concussion or even laceration of the optic nerve; paralysis of the sphincter pupillæ; suspension of the accommodation.

The nature and extent of the injury may be temporarily masked by hæmorrhage into the anterior chamber or the vitreous, or by the early occurrence of inflammation, or by the presence of old or recent opacity of the cornea or the crystalline lens. It should be remembered that lacerations of the retina and choroid from blows upon the sclerotic rarely, if ever, take place at the site of the blow, but are almost always at the posterior pole of the globe, and are more or less concentric with the optic nerve. More rarely, the rupture occurs in the anterior part of the choroid, but then there is also rupture in the posterior part and in the same meridian (Arlt).

Treatment must be to a large extent palliative and expectant only. The eye should be protected by a shade or by a light cooling compress. Complications and sequelæ must be treated according to their special indications.

Wounds of the sclerotic are, as a rule, very dangerous, because, first, of the degree of violence necessary to produce them; secondly, they are often attended by lesions of the cornea, iris, choroid, retina, crystalline lens, and vitreous; thirdly, they are frequently followed by grave pathological changes, such as inflammation, suppuration, cataract, detachment of the retina, glaucoma, or sympathetic ophthalmitis; and fourthly, they are often difficult to close, partly in consequence of the elasticity of the sclerotic, and partly from the tendency of the choroid or other of the intra-ocular contents to protrude into the wound and become entangled therein.

Wounds of the sclerotic may be *simple*—that is, involve only the sclerotic—or *complicated*. The *simple* wounds are—incised, contused, lacerated, punctured, ruptured, and gunshot. The *complicated* are those with rupture, or with protrusion, or even extrusion of the iris, ciliary body, choroid, retina, vitreous, suspensory ligament, or the crystalline lens itself; those with intra-ocular hæmorrhage, or with lodgment of a foreign body in the wound or within the globe.

Uncomplicated wounds of the sclerotic are comparatively rare, there being in most cases some prolapse of a portion of the uveal tract. When the wound is the result of great violence, and is inflicted by a large blunt instrument, there is almost always laceration of the choroid, with protrusion or extrusion of the vitreous or of the crystalline lens.

In blows with the fist, the rupture of the sclerotic does not take place at the point of impact, but in the ciliary region on the opposite side of the cornea; the usual situation being just outside the cornea and concentric with it, or opposite the interval between the superior and internal recti. But when the blow comes from above, then the lower part of the sclerotic may be torn. If the rupture take place quite close to the cornea, the conjunctiva is also torn, and the lens is forced out of the eye; but when it is more than, say, about one-twelfth of an inch away, the conjunctiva escapes, and the extruded contents of the globe lie under it as in a cyst.

It may be stated generally, that wounds of the sclerotic are dangerous in proportion to the degree of violence with which they were inflicted, the amount of protrusion and entanglement of the iris, choroid, &c., and their nearness to what is called 'the ciliary region.' Other things being equal, a small wound in the ciliary region is much more dangerous than a much larger wound elsewhere; and if there be entanglement of the iris or ciliary body, the risks are very greatly increased. So common is sympathetic ophthalmitis under such circumstances, that this part of the sclerotic is often spoken of as 'the dangerous region.' See SYMPATHETIC OPHTHALMITIS. Again, wounds of the sclerotic, with lodgment of a foreign body within the globe, are necessarily more serious than those without.

Treatment.—The first duty is to endeavour to ascertain the nature and extent of the injury, the second to calculate on the one hand the prospects of good and safe recovery, and of the risks of sympathetic ophthalmitis on the other.

If the eye be obviously destroyed, excision should be performed without delay. Perplexity only arises when, in spite of much apparent injury, there is a fair amount of sight, or when there is only a small wound but in a dangerous region. On the one hand, extensive laceration of the sclerotic may heal and a useful eye result; on the other, even a small wound in the ciliary region, with entanglement, is always, as already stated, a possible source of danger from sympathetic ophthalmitis.

If it be determined to try to save an eye, the lips of the wound should as far as practicable be cleared of all entanglements; all prolapsed tissues being returned or excised. If the wound be large, a stitch may be necessary to prevent escape of vitreous. This should be inserted by using a suture with a fine curved needle attached

to each end, and passing the needles separately from within outwards. The eyelids should then be closed by a light compress of boric or iodoform wool. Atropine, or eserine, according to the special indications, should be instilled two or three times a day.

In cases of rupture of the sclerotic, where there is complete extrusion of the lens under the unbroken conjunctiva, no attempt should be made to take away the lens for some weeks, so that the sclerotic may have time to heal. When this has taken place the conjunctiva may be divided, and the lens let out. If, however, the lens be entangled in the wound, it should be removed as soon as possible, in order to allow the lips of the sclerotic to fall into apposition.

In penetrating wounds of the sclerotic, with lodgment of a foreign body within the globe, excision will, as a rule, be called for, unless the foreign body be a fragment of iron and so placed as to be easily accessible to forceps or to the electro-magnet.

BURNS of the sclerotic are always accompanied by corresponding lesions to the CONJUNCTIVA, CORNEA, and EYELIDS, and do not therefore call for any special notice.

JOHN TWEEDY.

SCLEROTOMY. See GLAUCOMA.

SCOTOMA, a blind spot on the retina, the result of disease. See PERIMETRY.

SCROFULA or **STRUMA** is a condition of malnutrition of the tissues; it is not a disease but a diathesis—in other words, a tendency to certain forms of diseased action, most marked in infancy and youth, yet sometimes occurring in old age, when the body is naturally less well nourished, under the name *senile scrofula*.

The causes of this condition are—(1) Inheritance; (2) bad or insufficient food; (3) overcrowding, ill-ventilation, darkness and dampness of dwelling; (4) insalubrious climate.

(1) Parents suffering from, and in a less degree those who have suffered from, scrofula and its near relation tubercle, beget as a rule scrofulous children. The degree of scrofulosis, in different members of the offspring, varies with innumerable combinations of this cause with the other causes named above; as also with the health of either or both parents at the time of impregnation, and with the condition of the scrofulous or tuberculous mother during gestation. Probably, no child of scrofulous parents is entirely free of the taint, but, if all the other

above-named conditions be absent, it may escape any local manifestation. Probably, on the other hand, it may be affirmed that a sufficiently intense combination of the above with faulty hygiene will produce scrofula, in a child of parents however healthy.

(2) The milk of a scrofulous mother certainly increases the evil she has imparted; it is even probable that suckling by a scrofulous nurse may implant the diathesis in a congenitally healthy infant. The administration of farinaceous food, before the secretion of saliva is established, has considerable influence in the production of scrofula, or at least in calling forth scrofulous manifestations. This conclusion has been forced upon the writer by observation of several cases, notably of seven in which, when such mode of feeding was stopped, the outbreak ceased. Insufficient food with excess of starch, bad quality and monotony of diet, all have, in their degree, a like effect.

(3) That overcrowding is a potent generator of scrofula is indubitable. Breathing again and again an atmosphere already exhausted by other lungs is bad enough, even if those other lungs be healthy; but recent researches render it highly probable that scrofulous emanations from one person may produce that disease in another individual. Overcrowding implies also dirt, interfering with the action of the skin, and usually causes darkness. The action of light on the body is hardly sufficiently appreciated. The effect of its absence is analogous to the etiolation of plants.

(4) Scrofula is chiefly rife in climates which, like that of Britain, are damp, cold for the greater part of the year, and always uncertain. We know, however, from history, that two and even three hundred years ago 'the king's evil' was very prevalent, and it must be, in the present day, very difficult to apportion aright its cause between heredity and other conditions. Replies, however, to the writer's inquiries show that strumous families taking up residence in America, New Zealand, and Australia, (save in overcrowded parts of seaboard towns) so lose their proclivity, that the younger members, born strumous here, cease to exhibit manifestations after emigration, and that the parents procreate healthy children.

Pathology.—The strumous diathesis, without local manifestation, possesses no pathological anatomy hitherto demonstrable; it is probable, however, that the faulty nutrition mentioned in the opening sentence consists in some want of equilibrium, structural or functional, between the lym-

phatic rootlets or spaces and the other elements of the connective tissues. Whether this want of balance be primary, or whether it be dependent on some faulty condition of blood; or again whether it produces, or is produced by, minute anatomical variations from normal texture and fabric, more especially of the adenoid constituents of tissue, is not yet ascertained. But it is certain that this diathesis, when strongly developed, is marked by certain characteristics of external form, due to peculiarities in thickness and abundance, or in fineness and paucity, of the connective (areolar) tissue; and these characteristics are more especially impressed on such parts as are largely made up of lymphoid or adenoid structures.

These peculiarities are associated with a proclivity to follow up 'any slight and transient irritation by a chronic inflammatory process, which not only outlasts the irritation, but spreads or continues independently of it, usually resulting in suppuration or caseation, and rarely assuming the form of a pure hyperplasia' (Billroth). And in these conditions it is found that lymphatic tissues, notably the glands and such parts as contain abundance of adenoid elements, are especially vulnerable. But even the parts, thus suffering from strumous inflammation, betray no anatomical peculiarities differentiating them generically from parts affected with non-strumous chronic inflammation, until the resulting products undergo certain degenerations. It is, indeed, this tendency of the inflammation to continue, while its products are averse to organisation, which constitutes the characteristic of strumous manifestations, by producing a great accumulation of the most embryonic of inflammatory fabrics—granulation-tissue. This tissue is, however, common to all forms of subacute and chronic inflammations; in struma, its persistence, and therefore its amount, is alone to a certain extent peculiar.

But here attention must be called to certain minute bodies, very apt to form in the midst of this tissue, wherever interstitial cell-growth has much exceeded the rate of vessel-formation. Thus, non-vascular islets appear in which, equidistant on every side from the great vessels, nodules, are developed consisting externally of a delicate reticulum supporting lymphoid cells; further inward, of epithelioid cells; and centrally of larger branched cells, sometimes of giant-cells. For, wherever a portion of growing inflammatory product becomes extravascular, giant-cells commonly occur. These little spots are named by Rindfleisch, 'newly-

developed lymphatic follicles.' It is possible, however, that they indicate a tendency to organisation or to fibrillation—at least an abortive attempt at those actions, for Ziegler, by placing under the skin of dogs two cover-glasses, kept so far apart as to allow of granulation-tissue insinuating itself between them, found on their removal a number of very similar spots (only he called the epithelioid cells fibroblasts) formed of exactly similar elements. These bodies are therefore in no way distinctive of struma, they are found in old indolent ulcers, in the so-called proud-flesh (*caro luxurians*) of unhealed wounds and of burns, in the granulation-tissue surrounding sequestra, and in the thick granulation-material of very chronic synovitis. Nevertheless, though not distinctive of, they are most common in struma, because persistency of inflammatory products is most usual in that dyscrasia.

But to continue the life-history of granulation-tissue, which by its very nature must be merely transitional, and if it will not organise, must of necessity degenerate. Hence, unless fibrillation or cicatrisation set in, suppuration, together with much fatty degeneration, caseation, or tuberculisation will occur.

It is still unknown whether the cause of this imperfect tissue-nutrition is intrinsic in the tissues themselves or in the blood. Some support of the latter doctrine is afforded by two facts—that the blood of a large proportion of scrofulous persons contains an undue amount of lymphoid elements (leucocytes), and that two inflammatory manifestations of scrofula are rarely simultaneous. A belief in the humoral origin of the diathesis originated its treatment by setons and issues, to exhaust the blood of its peccant material.

The *diagnosis* of scrofula, the diathesis in contradistinction to the manifestations, depends on the appreciation of certain personal characteristics which are of two types, corresponding the one to fineness and paucity, the other to coarseness and abundance, of connective tissues. The former is marked by refinement and definition of the features. The curves of the lips, the nasal, aural, and tarsal cartilages are finely modelled. The conjunctiva and sclerotic are so thin that the pigment of the choroid, partially seen through them, imparts a bluish or pearl-grey colour to the white of the eye; the skin, clear and pure of tint, with cool-toned, ash-grey shadows, is so translucent that the bluish, wavy course of subjacent veins is plainly marked, as on the

upper eyelid, the temple, angle of the jaw, &c.; the luscious redness of the lips testifies to the same condition. The eyelashes are abundant and long—a fine down, often rather long, extends from the margin of the scalp-hair some way down the forehead, temples, and nape. The whole aspect is of refined but fragile beauty.

The other type is coarse and ugly. The head large and lumpy, bigger behind than before, is flanked by large, red, puffy ears; the jaws are prominent, the lips thick, ill-defined, and often cracked, sway clumsily apart. The nose is lumpish, the origin of the alæ ill-defined, the eyelids thick and clumsy, often even when not inflamed bordered with red, are frequently lined with dried Meibomian secretion clinging to the roots of sparse irregular lashes. The dull, unclean-looking skin is marked by large orifices of sebaceous ducts. The figure is usually ungainly, the joints and extremities large, the belly prominent; the hair coarse, either of a dull sandy colour or lustreless black. These descriptions are taken from the extremes of each type; to discriminate what degree of tendency either way may justify the practitioner in considering his patient scrofulous, requires acumen and experience. His judgment will be aided by considering the family history, the age of the patient, and the kind of malady he may be required to treat.

The manifestations of scrofula affect: (1) The skin; (2) mucous membranes; (3) lymphatic glands; (4) joints; (5) bones.

(1) The scalp is especially liable to eczema, tinea, and favus; the face to lupus; scrofulous ulcers, though chiefly choosing the neck, also occur at the bends of joints. Chilblain is said to be chiefly common in strumous persons, probably an error due to the obstinacy of all inflammations in such individuals.

(2) Phlyctenular ophthalmia, ulcerative corneitis, tinea tarsi, chronic catarrhs, catarrhal bronchitis, enlargement of tonsils and thickening of pharyngeal adenoid tissues, persistent coryza, ozæna, otorrhœa, purulent vulvitis and vaginitis.

(3) Enlargement of lymphatic glands, chiefly of the neck, probably induced in the first instance by teething, by one or more of the above irritations, or by an exanthem, especially by measles; thus every instance of an enlarged cervical gland is not, of necessity, strumous. The characteristics of the scrofulous enlargement are its very chronic character, its continuance long after the causation has ceased, its spread from gland to gland, and the tendency of the glands to

attain considerable size and to be the seats of protracted suppuration.

(4) Most chronic joint-affections, arising between the ages of a few months and eighteen years, are scrofulous, though they may originate (as some believe) in slight traumatism. The affection may commence in the synovial membrane, in the epiphysis, or in the epiphysial junction; in the last two conditions, the hyperæmia of rapid growth affording the primary irritation.

(5) Chronic carious affections of the bones occurring during early life are very generally strumous, absence of syphilis being verified. Spongy bones, as the bodies of vertebræ, the small bones of the carpus and tarsus, the epiphyses of long bones, are peculiarly prone to such affection; the hard cortex of long bones is less often attacked. A peculiar enlargement or distension from within of one or more phalanges bears the name of dactylitis; it is generally strumous, sometimes syphilitic. Rachitis is probably a scrofulous affection in the large majority of instances.

The combination of scrofula and syphilis is by no means uncommon; the manifestations of the mixed diatheses are severe and obstinate. Some writers believe that scrofula is degenerated syphilis, an unproven hypothesis.

The *treatment* of the scrofulous diathesis (the treatment of the above manifestations falls each under its own heading) is first of all improved hygiene, including—residence in large, not over-filled rooms, in preference by the seaside or at a somewhat high elevation on a dry gravelly soil, good ventilation, plenty of light and outdoor exercise. The diet must be regulated according to the age of the subject, and for that age must be of the most light and wholesome description. In the refined delicate forms, fatty matters should especially be pressed; ale or stout also may be given; they are less valuable, sometimes inadmissible, in the other form.

In the administration of drugs a similar distinction is desirable. The former kind of struma indicates cod-liver oil, maltine, iron—what may be called the blood-making tonics; the latter quinine or other bitters, mineral acids (nitro-hydrochloric), iodide of potassium; if iron be employed it should be given as the iodide. Alkalies, when the breath is sour, are often valuable. In this form of the diathesis, an occasional purge and alterative are essential to the treatment, especially when phlyctenular ophthalmia or the other above-named eye-affections are present, while the breath has an evil odour.

RICHARD BARWELL.

SCROTAL ELEPHANTIASIS.—The general subject of elephantiasis having been fully discussed elsewhere (*see* ELEPHANTIASIS ARABUM), it only remains here to consider the disease as specially affecting the scrotum, and to describe the measures which have been adopted for the cure of scrotal tumours of this nature.

Several varieties of the disease, as affecting the scrotum, are met with in India and other places where this malady is rife. They may be included in the following categories:—

1. Solid hypertrophies of the external genitals. These may be subdivided into:

(a) Simple scrotal elephantiasis. In most cases both penis and scrotum are implicated, but in some cases (i.) the skin of the penis and the prepuce are mainly involved, the scrotum being less affected; and in others (ii.) the scrotum is the principal or sole seat of disease. Under this head also come (iii.) labial tumours in the female. The labia majora are the most common seat of the disease, but the prepuce of the clitoris and the labia minora are also sometimes thickened. In rare cases, the tumour is principally situated in these latter parts.

(b) Complicated scrotal elephantiasis. The complication may consist of—(i.) Abscesses and ulcers; (ii.) stricture of the urethra; fistulæ, urethral, perineal, and anal; (iii.) large hydroceles and hæmatoceles; (iv.) hernia. These local complications materially affect the question of operation. (v.) The tumour may be in a state of acute hyperæmia, with accompanying fever, or (vi.) there may exist diseased conditions of the spleen, liver, kidneys, bowels, or adjoining lymphatic glands, or some constitutional disturbance or cachexy. These general complications also raise a doubt as to the propriety of resorting to operation.

2. Condylomatous growths simulating elephantiasis—met with both in male and female subjects.

3. Warty growths implicating the prepuce, penis, or scrotum, that have attained such a size as to constitute a tumour, or associated with some elephantoid thickening, also met with both in males and females.

4. Serpiginous ulcerations, consequent on chaneroid, and usually accompanied by some degree of elephantiasis.

5. Lymph-scrotum, consisting mainly or wholly of dilated lymphatic vessels, exuding spontaneously or on puncture a clear or milky fluid. The penis often remains healthy in this variety. Filarie are found

in this class of cases, but in none of the others. This form of disease is rarely, if ever, met with in the female.

It may be laid down, as a result of wide experience, that medicinal appliances are of little or no service in any of these forms of disease. A certain amount of relief may be obtained by recumbency, elastic bandages, and the local and general use of absorbents, more especially preparations of iodine; but, though the size of the tumour can be reduced by such agencies, the disease cannot be cured, and progressive enlargement will be found to proceed by means of those periodical attacks of fever, accompanied by local congestion and exudation, which characterise the development of the disease. It has also been established by a very large experience in India, China, and elsewhere, that by means of operation the local disease can be removed and the periodic fever which is associated with it cut short; and this without sacrifice of the essential organs of generation, or, in the great majority of cases, any risk of recurrence.

The questions which demand consideration here, therefore, are (1) in what circumstances is recourse to operation justifiable or desirable; and (2) what is the most approved and successful method of operating.

The inducements to remove the diseased parts by operation are these:—(a) The deformity and inconvenience caused by the growth, especially when it has attained a large size; (b) the sexual disability which it entails; (c) the discomfort caused by the periodical recurrence of fever; (d) the impairment of general health which results from these repeated attacks of pyrexia, which are often of severe character, and from the visceral disturbances, functional and structural, which are apt to be associated with a long-standing and progressive elephantiasis, and which undoubtedly tend to shorten life.

The earlier the tumour is removed, when it has once been fairly developed, the better, because the removal of a mass of moderate size, in a comparatively young subject, is a much less risky proceeding than the amputation of a large tumour in an old subject. Besides, the constitution and vitality of the subject are conserved by cutting short the fever, and preventing the development of visceral disturbance or decay.

The *contra-indications* of operation are:

a. *Old age.*—In the aged, sexual disableness is not a matter of much consequence, and if the tumour has, as often happens, become stationary in its growth, and the concomitant fever ceases to occur

or becomes less frequent and severe, operative interference, which is always more hazardous in the old, should be considered with more hesitation and caution.

b. Ill-health and visceral disease—more especially of heart, kidneys, or intestines. A weak or damaged heart, albuminuria, and chronic diarrhoea or dysentery, are prohibitive of operation. Cachexia and anaemia, however caused, also constitute serious objections to operating, and diabetes is absolutely prohibitory. Recent and acute enlargements of spleen and liver are likewise prohibitive, but chronic enlargement of either organ, if not accompanied with manifest impairment of health, is not a bar to removal by the knife.

c. Complications.—Reverting to the list of these given above—(i.) If the abscess be acute, it should be treated and cured before operation is resorted to; if chronic, or dependent on hæmatocele or diseased tunics, it may safely be removed along with the tumour. If the ulcer be small, and due to local irritation, or preceding abscess, operation need not be delayed. If large and due to general ill-health or extensive sloughing, caution and delay are advisable. (ii.) A stricture should be fully dilated before the operation is resorted to, because there is often difficulty in passing urine for a few days, and the use of a catheter is by no means an easy and safe matter unless the urethra is of normal size. Fistulae should, if possible, be cured by dilatation of the urethra or by free incision, accompanied, if necessary, by urethral dilatation; and, if they cannot be closed, operation should be declined. (iii.) Very large hydroceles and hæmatocèles enhance the risk of the operation, but are not a bar to it. If the patient is very old, the propriety of interference is more than doubtful; but in young and middle-aged subjects operation is advisable, and both diseases can be radically cured by the same procedure. (iv.) The existence of herniæ imports a very serious risk to life, and the simultaneous performance of an operation for the removal of the tumour and cure of the rupture has been proved, by experience, to be a very perilous practice. (v.) Operation should never be resorted to when the tumour is in a state of excitement, or while any febrile constitutional disturbance exists. Large size does not constitute so strong an objection to operation as some of the other considerations which have been adduced; for though it is true, generally, that the danger of removal is directly proportionate to the bulk of the mass, still, under improved methods of

operating, the risks depending on size have been greatly reduced, and experience has proved that immense tumours of this description, weighing, after removal, from 100 to 120 lbs., may be easily and successfully amputated, the period of convalescence and ultimate result being much the same as in the case of smaller masses.

The removal of scrotal elephantiasis has been practised in India since the beginning of the present century, and, at the present time, operations for this purpose are unhesitatingly performed in all countries and places where the disease is met with. The mortality in uncomplicated cases is inconsiderable, and the relief conferred complete and permanent. At first, the operation partook of the character of an amputation rather than a dissection. A clean sweep was made of the whole mass, including the genitals, at the level of the pubes, the vessels being tied as rapidly as possible, and the wound allowed to heal by granulation. Some surgeons transfixed the base of the tumour with a long catlin, and cut flaps from each side of its neck.

Rapidity of execution was considered to be the main point, for the double purpose of saving suffering and blood. Gradually, attempts were made to save the sexual organs. The penis was dissected out, and in small tumours the testes, when they appeared to be healthy; but, when the tumour was large and the testes diseased, no attempt was made to isolate and preserve them. The use of anæsthetics and of appliances for preventing hæmorrhage has allowed greater deliberation to be practised, and it is now very seldom necessary to sacrifice the testes, either on account of the size of the tumour or of disease of those organs. A curious attempt was made in the years 1836-39 by Dr. Esdale, of the Indian Medical Service, to induce anæsthesia by means of mesmerism, and a hospital was organised in Calcutta for the purpose of carrying out his experiments. The annals of this institution are exceedingly interesting, and appear to establish the fact that operations can be painlessly performed on mesmerised subjects. The process of mesmerising was, however, tedious and uncertain, and the introduction of chloroform rendered further experiment unnecessary.

The principles in accordance with which the operation is performed, in the present day, are as follows:—

1. To empty the tumour as completely as possible of blood.
2. To prevent bleeding during the operation.

8. To remove every scrap of diseased tissue and of tissue likely to become diseased.

4. To preserve the essential organs of generation.

5. To secure the testes in proper position by catgut-stitching.

6. To prevent putrefaction in the wound.

A few observations on each of these heads will suffice to describe the steps of the operation.

1. Elevation and elastic bandaging are the measures employed for anæmiating the tumour, and they are perfectly competent to do so. Ten to twenty minutes, according to the size of the mass, are sufficient for the purpose.

2. To prevent bleeding during the operation, an elastic cord should be tightly applied round the root of the tumour before the removal of the bandage, and secured in its position by being attached by tapes to a waist-belt. An easier and equally efficient plan is to take an elastic cord about three feet long, pass the centre of it round the loins, bring the ends over the brim of the pelvis, cross them twice over opposite sides of the neck of the tumour, and, finally, bring these together below the navel; the neck of the tumour will thus be tightly embraced by two turns of the cord on each side, crossing each other on the pubes and just in front of the anus.

3. Experience has proved that if any portion of the diseased tissue be left behind, recurrence is almost certain to take place. Even although the prepuce appears to be healthy, it should be removed close to the corona glandis; and as thickening is peculiarly apt to commence in the raphe of the perineum, that part should in most cases be freely removed by a V-shaped incision up to the verge of the anus. If any attempt is made to cover the penis or testes with flaps, these should be taken from the skin of the abdomen or thighs, and not from the neck of the tumour; but a satisfactory result can be secured in all cases without resort to flaps, which are prone to slough or suppurate and to initiate septic disturbance of the wound and constitution.

4. The first step of the actual operation consists in decorticating the penis. A director is passed into the preputial cavity as far as the reflexion of its lining membrane on to the corona glandis, and, by means of a strong bistoury, the prepuce is slit open by transfixion and cutting upwards. An incision is made from the root of the penis on its dorsum to meet and complete this cut. The penis is then freed by finger and

knife, the mucous membrane of the prepuce being carefully detached at the line of its reflexion. The isolation of the penis is completed as far as its suspensory ligament, which should not be injured. A vertical incision is now made from the pubes to the fundus of the tumour, over one cord and testis. By successive bold strokes these are exposed, and then dissected out by fingers and knife, and subsequently held out of the way by an assistant. The other testis is similarly dealt with. The three vertical incisions are then connected at their pubic terminations by two transverse cuts, which must be beyond the limit of the diseased tissue. A circular or oval incision is now made round the rest of the circumference of the neck of the tumour, and by rapid strokes the whole mass is removed. Vessels are now looked for. The largest will be found in the centre of the perineum and on each side of the pubes. By gradually loosening the cord, others will be observed to spring. All bleeding points should be carefully secured, and as many as thirty to forty ligatures may be required. The parts may now be trimmed if, in the hurry of operation, any diseased tissue has been left behind; and if the tunics are redundant or thickened, as much of them should be carefully dissected off as can be done without endangering the vitality of the testes.

5. The testes may now be stitched together by means of prepared catgut, and fastened in proper position by a few tacks of the same material. Depressions or pockets can be very easily made for their reception, by separating the deep layer of the superficial perineal fascia from the subjacent fat and areolar tissue. The skin can then be drawn over them from each side to a considerable extent, by means of a continuous catgut suture.

6. The prevention of putrefaction in an extensive wound, from which there is necessarily a very profuse discharge, situated in such close proximity to the urethral and anal orifices, and to which it is difficult to maintain dressings in close contact, is by no means an easy task.

The use of the spray during operation, or of thorough irrigation with carbolic or sublimate lotion immediately after it, and the dusting of the wound with iodoform, followed by the careful application of antiseptic dressings, suffice in most cases to maintain asepsis and to prevent suppuration. The plan of dressing employed by the writer is—(1) The application to the raw surface of boracic ointment spread on thin gauze; (2) placing outside of this

a piece of boracic lint sufficient to overlap the whole wound and a margin of skin beyond; (3) outside this are applied folds of carbolic gauze, which extend beyond the margins of the wound on to the pubes and thighs; (4) a sheet of waterproof or oiled paper is spread over the dressings, and the whole secured by careful bandaging. The dressings are changed daily for the first ten days or so, while the discharge is profuse and the wound large; then every second or third day, as the wound contracts and the exudation from it diminishes.

The process of repair consists in the filling up of the wound-cavity with lymph, which glazes the wound and forms a medium of union between the testes, and between these and the surface of the perineum. When this lymph undergoes vascularisation and organisation, granulations form and cicatrisation advances over the wound from the borders of the divided skin and preputial mucous membrane. The process of repair is tedious, occupying from six weeks to two months. Care must be taken to keep the penis free, as it is apt to be embedded in and retracted into the mass of granulation-tissue. Should such a result threaten, the granulations at its root may be broken down by the finger-nail, or divided by scissors if they have become firm. The ultimate result of the operation is, in the great majority of cases, satisfactory. Skin is dragged by the process of cicatrisation from the thigh to form a seemly and useful substitute for the amputated scrotum, and the penis acquires a fresh covering of cicatricial epidermis. The sexual functions are restored, and both health and comfort re-established.

The operation above described is applicable to all the forms of elephantiasis which have been specified. If the skin of the penis is quite healthy, the scrotum may be removed alone by a circular incision round its neck, the testes being dissected out as the incision is deepened.

Labial tumours in the female are removed in accordance with the same principles. If very large, their base may be transfixed and tied with whipcord before amputation is commenced; but, in most cases, the prompt use of *forci-pressure* forceps and sponge pressure suffice to prevent much loss of blood. The edges of the skin can be approximated or brought into contact by sutures, and the process of repair thus very materially shortened. K. McLEOD.

SCROTAL SWELLINGS, Diagnosis of.—In the examination of a scrotal swelling certain points must be kept clearly in

view, and this may be done by the surgeon asking himself the following questions:—Is this swelling a scrotal one proper, or does it extend into the inguinal canal or abdomen? Is it reducible or no, and, if reducible, is this real or only apparent? Is it fluid or solid? What are its relations to the testis, epididymis, or cord? Is any part of it translucent? Is it of the same consistence all over? What has been its rate of progress?

Scrotal swellings may be divided into: (a) those which occupy more or less of the inguinal region as well as the scrotum, and (b) those confined to the scrotum.

(a) The chief swellings here are:—1, scrotal hernia; 2, scrotal hernia with hydrocele; 3, infantile hydrocele; 4, congenital hydrocele (occasional); 5, hydrocele of cord (occasional); 6, incompletely descended testis; 7, large varicoceles (rare); 8, combined hydroceles—e.g. of the tunica vaginalis and of the cord (rare); 9, new-growths of the cord—e.g. lipomata, malignant (still rarer).

The method of handling any scrotal swelling is important. The left hand should take hold of the upper part or neck of the swelling, so as to steady the tumour; then any impulse on coughing can be felt for, and, at the same time, by a gentle downward squeezing movement, the rest of the swelling is pressed forward, and the scrotal tissues over it stretched, the fingers of the right hand being free to percuss, or otherwise examine into the nature of the swelling.

1. *Hernia* is one of the commonest scrotal swellings, being met with in children as well as later on in life. It may be known by the impulse at the neck, its ready reducibility (usually) on the patient's lying down, with slip or gurgle, the facility with which now the external ring and cord can be felt, its speedy descent when the patient stands up and coughs, and its lack of translucency. The thickened tissue felt in the scrotum after the return of the hernia is merely the sac, and not to be taken for anything more abnormal. If the hernia is irreducible, there will still be impulse, the feeling of coils of bowel or of granular omentum; and the irreducibility will be either temporary—due to neglect of the bowels or disordered digestion—or permanent, owing to repeated 'bowel attacks,' accompanied by slight colicky pains.

2. A hernia is frequently complicated with hydrocele (see below).

3. *Infantile Hydrocele*.—A sub-variety of the congenital, in which the fluid usually extends as far as the external abdominal

ring. Its smooth outline, transparency, and history are main points, while its irreducibility, and fluctuation without gurgling, distinguish it from hernia.

4. *Congenital Hydrocele*.—This is dull on percussion and translucent, the impulse is much less distinct; its reduction is generally perfectly easy when the patient is recumbent, but occasionally requires steady pressure; it is unaccompanied by any slip or gurgle unless a congenital hernia is also present.

5. *Hydrocele of the Cord*.—The fluid here is usually encysted, and is most frequently due to part of the processus funicularis remaining unobliterated, more rarely to some independent collection of fluid becoming encysted in the connective tissue of the cord. In the former case it will have been noticed from birth or from early childhood, in the latter it may date from an injury or strain. The swelling is often mistaken for a hernia, and a truss ordered. The following are the chief distinguishing points:—Usually oval in shape, the swelling is found to be limited above and below—i.e. when drawn down it has no neck; so, too, when drawn down, the impulse is less and less distinct. It cannot be completely and distinctly returned; though often tense, fluctuation can sometimes be made out; and by using a candle in a dark room and lifting the swelling up, translucency can usually be observed.

6. A *retained testis* often forms a swelling in the groin or upper part of the scrotum. Its shape, sensitiveness, mobility, and the empty scrotum are decisive. If retained in the inguinal region, a testis may be the seat of orchitis in recurrent crippling attacks. Some of these may be so acute that the swelling may simulate a strangulated hernia. Thus the attack may have come on after a strain, the patient persisting in his statement that he has always had a rupture which came down and went up again. The parts are exquisitely tender, and do not admit of handling; most acute pain may be present in the lower part of the belly, accompanied by nausea and constipation. On careful examination the scrotum is empty, no truss has ever fitted, the rupture has never been really reducible, and unless peritonitis be present, which is not common, the symptoms will be less urgent than those of strangulation; thus the vomiting will not be more than bilious, and flatus at least will be passed. If, after a few hours, treatment does not clear up the case, the diagnosis should be made certain by antiseptic exploration.

A testis retained in the inguinal region is liable, after repeated attacks of inflammation, to become the seat of malignant disease, and form a swelling in the groin and upper part of the scrotum. It will be known by the absence of the testis from the scrotum, the history of repeated inflammatory attacks, the steady increase in size, and painfulness of a swelling, which, chiefly solid, shows fluid at one or more spots. Lastly, the absence of a testis from the scrotum will prevent the surgeon from mistaking a retained testis, which is the site of acute epididymitis, for a bubo.

(b) The chief scrotal swellings proper are:—1, hydrocele (vaginal and encysted); 2, hæmatocele; 3, orchitis; 4, syphilitic testis; 5, epididymitis; 6, strumous testis; 7, new-growths; 8, varicocele.

1. A *vaginal hydrocele* is known by the absence of impulse, by its pyriform shape, fluctuation, and almost unvarying translucency. The testis is at the back, as shown by its sensitiveness and opacity. The increase has been slow, painless, and usually occurs in patients of middle or later life, though it is not uncommon in younger men after strain, injury, or in association with acute epididymitis.

An *encysted hydrocele* is recognised by its position to the outer side of, and rather anterior to the testis, its fluctuation, its shape—globose rather than pyriform—and much slower growth.

Swellings in which different hydroceles are combined—e.g. one of the tunica vaginalis and an encysted hydrocele—are met with, and may at first be difficult of diagnosis. A very common combination is hydrocele of the tunica vaginalis with scrotal hernia, and in the later stages of this combination, when the two swellings have come into close contact with each other, the diagnosis is a matter of some doubt at first, especially when the hernia is irreducible; but if attention is paid to the points already given, there will be no real difficulty.

2. A *hæmatocele* will be known, when at all recent, by its rapid onset after a blow or the tapping of a hydrocele; its condition, at first fluid, then more solid; its weight and want of translucency, and the position of the testicle at the back. A little later, especially if the patient get about, tenderness, redness, and cedema of the scrotum will point to an inflamed hæmatocele.

3. *Orchitis*, or inflammation of the testis itself, may be met with as an acute, sub-acute, or chronic affection. The acute is usually due to a blow; it is rare, though epididymitis (owing to some urethral cause)

is often called orchitis. Subacute orchitis may be due to a blow, the congestion which goes with ungratified and unrestrained sexual desires, or it may occur in the course of an attack of gout or mumps.

Chronic orchitis may be confused with an old hydrocele, hæmatocele, or some of the new-growths of the testis.

4. *Syphilitic orchitis* may present itself as a diffuse chronic inflammation of the testis two or three years after contagion, or later on as a gummatous affection, or the two may be combined. In the former, the swelling may reach the size of a large egg or small orange, the smooth heavy mass being devoid of testicular sensation; both testes may be affected. In the gummatous orchitis the enlargement is less, and the surface may be knotty. Both are insidious, both may be accompanied by subsequent wasting.

5. *Epididymitis*, in its acute and subacute forms, is one of the commonest of scrotal swellings. Its diagnosis will be aided by remembering that it is nearly always due to some urethral irritation, most frequently gonorrhœa. It shows itself as a rapidly forming swelling, acute and tender, at the outer and back part of the testis, from which at first it is separated by a distinct furrow. The swelling is flat-sided, the scrotal tissues red and a little cedematous, and some fluid is usually present in the tunica vaginalis. Nausea, chilliness, pyrexia accompany it, and probably some deep-seated pain has been noticed creeping along the inguinal region and cord, and the vas deferens is thickened and tender.

6. *Strumous testis*.—This obstinate affection usually begins as a painless insidious nodule in the head or tail of the epididymis, which tends ultimately to soften and gradually to perforate the scrotal tissues which have become adherent to it. The condition of other parts—the testis, vas deferens, and prostate—should be examined into for thickening and enlargement: the bladder for cystitis, and the kidney for any evidence of strumous pyelitis. A history of chronic inflammation of joints and glands, or of phthisis, will aid in the diagnosis.

7. *New-growths of testis*.—Where these are rapid in their growth and results, as in the case of encephaloid carcinoma or round-celled sarcoma, the diagnosis is not difficult; but where the progress is slow, where for some time the consistency keeps firm, the cord is not involved, and the patient's health remains good, as is often the case in a spindle-celled sarcoma, a chondro-sarcoma, or in the earlier stages of 'cystic disease

of the testis,' the diagnosis is by no means so easy, especially as the history of repeated slight injuries may suggest orchitis. See TESTIS, Diseases of the.

8. *Varicocele*.—This, one of the commonest of the affections in the scrotum, will be known by the soft, worm-like, bluish coils of enlarged veins around and along the cord, the relaxed scrotum, and the dropped testicle. When extending into the canal, a varicocele shows impulse when the patient coughs; but this is less distinct than in hernia, and alteration in the size of the swelling is only noticed when the patient has been on his feet or resting for some considerable time. It is not completely reducible, and if the surgeon, having got up all he can while the patient is lying down, place his finger over the external abdominal ring, and tell the patient to rise, the swelling gradually reappears below the finger.

W. H. A. JACOBSON.

SCROTUM, Injuries and Diseases of the.—*Contusions* may occur from falls on the edge of a chair, on a rail, pommel of saddle, &c, and owing to the looseness of the tissues, much extravasation may take place. This is often complicated with hæmatocele, but, if existing by itself, may be known by its superficial position and its crossing the scrotal raphe.

Treatment.—In severe cases absolute rest in bed should be enforced, and the scrotum be kept well raised by a suspensory bandage and a small firm pillow. A smart purge should be given, and its action gently kept up, and a cooling lotion—lead, or lead and opium—constantly applied. Where the coexistence of a hæmatocele is suspected, ice should be applied, but, except in strong and healthy subjects, it will be well to place a layer of lint next the skin. If the ice does not produce material relief within two hours, its use should be discontinued, and lotions, at first cold, then warm, gradually substituted, in order to prevent too rapid changes and sloughing of the scrotum.

If, later on, any thickening of the scrotum be left, it will be well to rub in oleate of mercury (5 p.c.), or to use counter-irritation by iodine.

Wounds.—These may be incised or lacerated, the results of falls, machinery accidents, or attempts at mutilation. In the case of a recent incised wound, after cleansing the parts and arresting hæmorrhage, it will be well, owing to the disturbing effect of the dartos, to draw the edges of the skin together with fine silk sutures, not passing them sufficiently deeply to

open up the cellular tissue. Before inserting these, the testicles, if protruding, must be carefully replaced, and the scrotal tissues relaxed by warmth. Cold lotions should be applied after insertion of the stitches, and the parts be kept well supported to prevent any bagging and strain on the stitches.

In lacerated wounds, stitches must be used with great caution and only in a recent case, a few points of fine silk being employed. Warm lotions, cotton-wool, and even support are here indicated, any stitches used being removed early, and punctures made on the appearance of œdema.

Edema, Cellulitis, and Erysipelas of the Scrotum tend to run into and complicate each other. They occur chiefly in infants, especially weakly ones of lowly life, and in adults when depressed in health, ill-fed, and exposed to cold, and often in the subjects of visceral disease. The exciting cause is injury, or a much slighter matter, a patch of erythema, an abrasion, fistula, or even merely the trickling of urine. The chief dangers are, in the case of infants, peritonitis, if the processus funicularis be patent, and, at any time of life, sloughing and septicæmia. The scrotum and skin of the penis are, no doubt, well supplied with blood, but the vessels come from a considerable distance, are flexuous, and but ill-supported in the necessarily yielding cellular tissue of the parts, the meshes of this tissue being, furthermore, easily loaded with inflammatory products.

Cases of œdema, cellulitis, and erysipelas of the scrotum are to be carefully distinguished from those of extravasation of urine, which they closely simulate, by the absence of any previous urinary trouble, and by the facility with which a catheter can be passed. The history of a painful, localised swelling in the middle line—e.g. a perineal abscess observed before the appearance of the more general swelling—will also be absent. As long as the œdema or redness is slight, elevation of the parts, keeping them very dry and dusted with zinc and starch powder, will be sufficient, locally. A little later, multiple punctures will probably be required, and when the parts are not only tense and glossy but brawny, free incisions should be made into the cellular tissue. In making these, it should be remembered that the vitality of the parts is already seriously impaired, and that needless incisions will not only, by further interfering with the blood-supply, increase the liability to sloughing, but may also excite further diffuse inflammation. For this reason punctures will probably be sufficient

in children, and in adults it will not be needful to make more than two incisions on either side, one close to the raphè, about three inches long, carried well down into the lower and posterior part, and another somewhat shorter and external to this. The hæmorrhage will at first be free, but if any spurting vessels are twisted or ligatured, the oozing will be checked by pressure applied by a pad of lint and carbolic oil, over which iodoform and tannin have been dusted. Later on the carbolic oil may be replaced by saturated lotions of boracic acid, or an ointment of vaseline ʒj., ol. eucalypt. fʒj., iodof. ʒj.; prominent or weakly granulations being treated occasionally with lotions containing copper sulphate or nitric acid. The general treatment requires to be of a supporting kind.

Sloughing and Gangrene may follow on erysipelas of the scrotum, quite independently of any extravasation of urine, its most frequent cause. Other, but much rarer causes, are frostbite and the exhaustion of prolonged exanthemata. The changes in colour and temperature are quite unmistakable.

If there is no evidence of lesion requiring incisions, the part should be kept well wrapped up in cotton wool, in which a little powdered iodoform has been dusted, lint soaked in eucalyptus or carbolic acid oil, or poultices of yeast, charcoal, or chlorinated soda made use of, it being remembered that, as in other cases of gangrene, poultices, to do any good, must be changed frequently, and that this has the disadvantage of entailing frequent exposure. Later on, sloughs should be clipped away, and stimulating dressings, such as resin and tinct. benzoini co. made use of, and healing hastened by occasional applications of silver nitrate (gr. x.—fʒj.), and skin-grafting. The reparative power of the scrotum is well known; very large losses will be replaced, though the skin is now thinner, smoother, and less supple than before. Sloughing of the scrotum, and the milder inflammatory affections which may precede it—e.g. œdema and erysipelas—are usually accompanied by symptoms pointing to asthenia, and the treatment should be, from the first, supporting.

New-Growths in the Scrotum.—Of these epithelioma is the most common—‘chimney-sweep’s cancer’—though this disease is on the decline, owing, probably, to the use of machines in chimney-sweeping.

It usually begins as a small wart on, or as a pea-like swelling in, the skin, the disease starting in the latter case from the

irritation of a sebaceous gland or hair-follicle. In either case induration and ulceration follow sooner or later, though often insidiously, the ulceration presenting the characters of epithelioma elsewhere, viz. edges indurated, everted, and sinuous, the base of uneven depth, here greyish and sloughing, there prominent with unhealthy granulations. If left to itself, the ulceration may go so far as to expose and destroy the testicles, and involve the glands in the groin in large malignant ulcers.

Treatment.—This should be always early and free removal by the knife, aided, if need be, by caustics, such as zinc chloride and flour. As an aid to removal, a metal catheter may be kept in the urethra, and if the testicles are involved leave should be got, before the operation, to extirpate them if necessary. The inguinal glands, if merely enlarged, not densely hard, and if still movable, may be watched for a while. Where removal of the disease is not possible, the surgeon can only support the strength, relieve pain, and diminish fœtor.

A few other scrotal new-growths are very occasionally met with, viz. fibro-cystic, fatty, and fibrous; these last, though originating in the scrotum, often becoming attached to the epididymis or testis.

W. H. A. JACOBSON.
